## I. Tutorial

| 1. Getting Started | 1 |
| 1.1. Installation | 1 |
| 1.2. Architectural Fundamentals | 1 |
| 1.3. Creating a Database | 2 |
| 1.4. Accessing a Database | 3 |
| 2. The SQL Language | 6 |
| 2.1. Introduction | 6 |
| 2.2. Concepts | 6 |
| 2.3. Creating a New Table | 6 |
| 2.4. Populating a Table With Rows | 7 |
| 2.5. Querying a Table | 8 |
| 2.6. Joins Between Tables | 10 |
| 2.7. Aggregate Functions | 12 |
| 2.8. Updates | 13 |
| 2.9. Deletions | 14 |
| 3. Advanced Features | 15 |
| 3.1. Introduction | 15 |
| 3.2. Views | 15 |
| 3.3. Foreign Keys | 15 |
| 3.4. Transactions | 16 |
| 3.5. Inheritance | 18 |
| 3.6. Conclusion | 19 |

## II. The SQL Language

| 4. SQL Syntax | 21 |
| 4.1. Lexical Structure | 23 |
| 4.1.1. Identifiers and Key Words | 23 |
| 4.1.2. Constants | 24 |
| 4.1.2.1. String Constants | 24 |
| 4.1.2.2. Dollar-Quoted String Constants | 25 |
| 4.1.2.3. Bit-String Constants | 26 |
| 4.1.2.4. Numeric Constants | 26 |
| 4.1.2.5. Constants of Other Types | 27 |
| 4.1.3. Operators | 28 |
| 4.1.4. Special Characters | 28 |
| 4.1.5. Comments | 29 |
5. Data Definition

5.1. Table Basics .............................................................................................................. 39
5.2. Default Values ........................................................................................................... 40
5.3. Constraints ................................................................................................................ 41
   5.3.1. Check Constraints ........................................................................................ 41
   5.3.2. Not-Null Constraints .................................................................................... 43
   5.3.3. Unique Constraints ....................................................................................... 44
   5.3.4. Primary Keys ................................................................................................... 44
   5.3.5. Foreign Keys ...................................................................................................... 45
5.4. System Columns ......................................................................................................... 48
5.5. Modifying Tables ....................................................................................................... 49
   5.5.1. Adding a Column ........................................................................................ 49
   5.5.2. Removing a Column ..................................................................................... 50
   5.5.3. Adding a Constraint ..................................................................................... 50
   5.5.4. Removing a Constraint ................................................................................ 51
   5.5.5. Changing a Column’s Default Value ............................................................ 51
   5.5.6. Changing a Column’s Data Type ................................................................. 51
   5.5.7. Renaming a Column .................................................................................... 52
   5.5.8. Renaming a Table ....................................................................................... 52
5.6. Privileges .................................................................................................................. 52
5.7. Schemas ..................................................................................................................... 53
   5.7.1. Creating a Schema ...................................................................................... 53
   5.7.2. The Public Schema ...................................................................................... 54
   5.7.3. The Schema Search Path .......................................................................... 54
   5.7.4. Schemas and Privileges ............................................................................. 56
   5.7.5. The System Catalog Schema .................................................................... 56
   5.7.6. Usage Patterns ............................................................................................ 56
   5.7.7. Portability ...................................................................................................... 57
5.8. Inheritance .................................................................................................................. 57
   5.8.1. Caveats .......................................................................................................... 60
5.9. Partitioning ................................................................................................................ 60
   5.9.1. Overview ....................................................................................................... 60
   5.9.2. Implementing Partitioning .......................................................................... 61
   5.9.3. Managing Partitions .................................................................................... 64
   5.9.4. Partitioning and Constraint Exclusion ...................................................... 65
   5.9.5. Alternative Partitioning Methods ............................................................... 66
   5.9.6. Caveats .......................................................................................................... 67
5.10. Other Database Objects .......................................................................................... 67

Preface

This book is the official documentation of PostgreSQL. It is being written by the PostgreSQL developers and other volunteers in parallel to the development of the PostgreSQL software. It describes all the functionality that the current version of PostgreSQL officially supports.

To make the large amount of information about PostgreSQL manageable, this book has been organized in several parts. Each part is targeted at a different class of users, or at users in different stages of their PostgreSQL experience:

• Part I is an informal introduction for new users.
• Part II documents the SQL query language environment, including data types and functions, as well as user-level performance tuning. Every PostgreSQL user should read this.
• Part III describes the installation and administration of the server. Everyone who runs a PostgreSQL server, be it for private use or for others, should read this part.
• Part IV describes the programming interfaces for PostgreSQL client programs.
• Part V contains information for advanced users about the extensibility capabilities of the server. Topics are, for instance, user-defined data types and functions.
• Part VI contains reference information about SQL commands, client and server programs. This part supports the other parts with structured information sorted by command or program.
• Part VII contains assorted information that might be of use to PostgreSQL developers.

1. What is PostgreSQL?

PostgreSQL is an object-relational database management system (ORDBMS) based on POSTGRES, Version 4.2\(^1\), developed at the University of California at Berkeley Computer Science Department. POSTGRES pioneered many concepts that only became available in some commercial database systems much later.

PostgreSQL is an open-source descendant of this original Berkeley code. It supports a large part of the SQL standard and offers many modern features:

• complex queries
• foreign keys
• triggers
• views
• transactional integrity
• multiversion concurrency control

Also, PostgreSQL can be extended by the user in many ways, for example by adding new

• data types
• functions
• operators
• aggregate functions
• index methods

• procedural languages

And because of the liberal license, PostgreSQL can be used, modified, and distributed by everyone free of charge for any purpose, be it private, commercial, or academic.

2. A Brief History of PostgreSQL

The object-relational database management system now known as PostgreSQL is derived from the POSTGRES package written at the University of California at Berkeley. With over a decade of development behind it, PostgreSQL is now the most advanced open-source database available anywhere.

2.1. The Berkeley POSTGRES Project

The POSTGRES project, led by Professor Michael Stonebraker, was sponsored by the Defense Advanced Research Projects Agency (DARPA), the Army Research Office (ARO), the National Science Foundation (NSF), and ESL, Inc. The implementation of POSTGRES began in 1986. The initial concepts for the system were presented in *The design of POSTGRES*, and the definition of the initial data model appeared in *The POSTGRES data model*. The design of the rule system at that time was described in *The design of the POSTGRES rules system*. The rationale and architecture of the storage manager were detailed in *The design of the POSTGRES storage system*.

POSTGRES has undergone several major releases since then. The first "demoware" system became operational in 1987 and was shown at the 1988 ACM-SIGMOD Conference. Version 1, described in *The implementation of POSTGRES*, was released to a few external users in June 1989. In response to a critique of the first rule system (*A commentary on the POSTGRES rules system*), the rule system was redesigned (*On Rules, Procedures, Caching and Views in Database Systems*), and Version 2 was released in June 1990 with the new rule system. Version 3 appeared in 1991 and added support for multiple storage managers, an improved query executor, and a rewritten rule system. For the most part, subsequent releases until Postgres95 (see below) focused on portability and reliability.

POSTGRES has been used to implement many different research and production applications. These include: a financial data analysis system, a jet engine performance monitoring package, an asteroid tracking database, a medical information database, and several geographic information systems. POSTGRES has also been used as an educational tool at several universities. Finally, Illustra Information Technologies (later merged into Informix², which is now owned by IBM³) picked up the code and commercialized it. In late 1992, POSTGRES became the primary data manager for the Sequoia 2000 scientific computing project⁴.

The size of the external user community nearly doubled during 1993. It became increasingly obvious that maintenance of the prototype code and support was taking up large amounts of time that should have been devoted to database research. In an effort to reduce this support burden, the Berkeley POSTGRES project officially ended with Version 4.2.

2.2. Postgres95

In 1994, Andrew Yu and Jolly Chen added a SQL language interpreter to POSTGRES. Under a new name, Postgres95 was subsequently released to the web to find its own way in the world as an open-source descendant of the original POSTGRES Berkeley code.

Postgres95 code was completely ANSI C and trimmed in size by 25%. Many internal changes improved performance and maintainability. Postgres95 release 1.0.x ran about 30-50% faster on the Wisconsin Benchmark compared to POSTGRES, Version 4.2. Apart from bug fixes, the following were the major enhancements:

- The query language PostQUEL was replaced with SQL (implemented in the server). Subqueries were not supported until PostgreSQL (see below), but they could be imitated in Postgres95 with user-defined SQL functions. Aggregate functions were re-implemented. Support for the GROUP BY query clause was also added.

- A new program (psql) was provided for interactive SQL queries, which used GNU Readline. This largely superseded the old monitor program.

- A new front-end library, libpgtcl, supported Tcl-based clients. A sample shell, pgtclsh, provided new Tcl commands to interface Tcl programs with the Postgres95 server.

- The large-object interface was overhauled. The inversion large objects were the only mechanism for storing large objects. (The inversion file system was removed.)

- The instance-level rule system was removed. Rules were still available as rewrite rules.

- A short tutorial introducing regular SQL features as well as those of Postgres95 was distributed with the source code

- GNU make (instead of BSD make) was used for the build. Also, Postgres95 could be compiled with an unpatched GCC (data alignment of doubles was fixed).

2.3. PostgreSQL

By 1996, it became clear that the name “Postgres95” would not stand the test of time. We chose a new name, PostgreSQL, to reflect the relationship between the original POSTGRES and the more recent versions with SQL capability. At the same time, we set the version numbering to start at 6.0, putting the numbers back into the sequence originally begun by the Berkeley POSTGRES project.

Many people continue to refer to PostgreSQL as “Postgres” (now rarely in all capital letters) because of tradition or because it is easier to pronounce. This usage is widely accepted as a nickname or alias.

The emphasis during development of Postgres95 was on identifying and understanding existing problems in the server code. With PostgreSQL, the emphasis has shifted to augmenting features and capabilities, although work continues in all areas.

Details about what has happened in PostgreSQL since then can be found in Appendix E.

3. Conventions

This book uses the following typographical conventions to mark certain portions of text: new terms, foreign phrases, and other important passages are emphasized in italics. Everything that represents
input or output of the computer, in particular commands, program code, and screen output, is shown in a monospaced font (example). Within such passages, italics (example) indicate placeholders; you must insert an actual value instead of the placeholder. On occasion, parts of program code are emphasized in bold face (example), if they have been added or changed since the preceding example.

The following conventions are used in the synopsis of a command: brackets ([ and ]) indicate optional parts. (In the synopsis of a Tcl command, question marks (?) are used instead, as is usual in Tcl.) Braces ({ and } ) and vertical lines (|) indicate that you must choose one alternative. Dots ( . . . ) mean that the preceding element can be repeated.

Where it enhances the clarity, SQL commands are preceded by the prompt =>. and shell commands are preceded by the prompt $. Normally, prompts are not shown, though.

An administrator is generally a person who is in charge of installing and running the server. A user could be anyone who is using, or wants to use, any part of the PostgreSQL system. These terms should not be interpreted too narrowly; this book does not have fixed presumptions about system administration procedures.

4. Further Information

Besides the documentation, that is, this book, there are other resources about PostgreSQL:

FAQs
The FAQ list contains continuously updated answers to frequently asked questions.

Web Site
The PostgreSQL web site carries details on the latest release and other information to make your work or play with PostgreSQL more productive.

Mailing Lists
The mailing lists are a good place to have your questions answered, to share experiences with other users, and to contact the developers. Consult the PostgreSQL web site for details.

Yourself!
PostgreSQL is an open-source project. As such, it depends on the user community for ongoing support. As you begin to use PostgreSQL, you will rely on others for help, either through the documentation or through the mailing lists. Consider contributing your knowledge back. Read the mailing lists and answer questions. If you learn something which is not in the documentation, write it up and contribute it. If you add features to the code, contribute them.

5. Bug Reporting Guidelines

When you find a bug in PostgreSQL we want to hear about it. Your bug reports play an important part in making PostgreSQL more reliable because even the utmost care cannot guarantee that every part of PostgreSQL will work on every platform under every circumstance.

The following suggestions are intended to assist you in forming bug reports that can be handled in an effective fashion. No one is required to follow them but doing so tends to be to everyone’s advantage.

We cannot promise to fix every bug right away. If the bug is obvious, critical, or affects a lot of users, chances are good that someone will look into it. It could also happen that we tell you to update to a newer version to see if the bug happens there. Or we might decide that the bug cannot be fixed before some major rewrite we might be planning is done. Or perhaps it is simply too hard and there are more important things on the agenda. If you need help immediately, consider obtaining a commercial support contract.

5.1. Identifying Bugs

Before you report a bug, please read and re-read the documentation to verify that you can really do whatever it is you are trying. If it is not clear from the documentation whether you can do something or not, please report that too; it is a bug in the documentation. If it turns out that a program does something different from what the documentation says, that is a bug. That might include, but is not limited to, the following circumstances:

- A program terminates with a fatal signal or an operating system error message that would point to a problem in the program. (A counterexample might be a “disk full” message, since you have to fix that yourself.)
- A program produces the wrong output for any given input.
- A program refuses to accept valid input (as defined in the documentation).
- A program accepts invalid input without a notice or error message. But keep in mind that your idea of invalid input might be our idea of an extension or compatibility with traditional practice.
- PostgreSQL fails to compile, build, or install according to the instructions on supported platforms.

Here “program” refers to any executable, not only the backend server.

Being slow or resource-hogging is not necessarily a bug. Read the documentation or ask on one of the mailing lists for help in tuning your applications. Failing to comply to the SQL standard is not necessarily a bug either, unless compliance for the specific feature is explicitly claimed.

5.2. What to report

The most important thing to remember about bug reporting is to state all the facts and only facts. Do not speculate what you think went wrong, what “it seemed to do”, or which part of the program has a fault. If you are not familiar with the implementation you would probably guess wrong and not help us a bit. And even if you are, educated explanations are a great supplement to but no substitute for facts. If we are going to fix the bug we still have to see it happen for ourselves first. Reporting the bare facts is relatively straightforward (you can probably copy and paste them from the screen) but all too often important details are left out because someone thought it does not matter or the report would be understood anyway.

The following items should be contained in every bug report:

- The exact sequence of steps from *program start-up* necessary to reproduce the problem. This should be self-contained; it is not enough to send in a bare `SELECT` statement without the preceding `CREATE TABLE` and `INSERT` statements, if the output should depend on the data in the tables.
We do not have the time to reverse-engineer your database schema, and if we are supposed to make up our own data we would probably miss the problem.

The best format for a test case for SQL-related problems is a file that can be run through the psql frontend that shows the problem. (Be sure to not have anything in your ~/.psqlrc start-up file.) An easy start at this file is to use pg_dump to dump out the table declarations and data needed to set the scene, then add the problem query. You are encouraged to minimize the size of your example, but this is not absolutely necessary. If the bug is reproducible, we will find it either way.

If your application uses some other client interface, such as PHP, then please try to isolate the offending queries. We will probably not set up a web server to reproduce your problem. In any case remember to provide the exact input files; do not guess that the problem happens for “large files” or “midsize databases”, etc. since this information is too inexact to be of use.

- The output you got. Please do not say that it “didn’t work” or “crashed”. If there is an error message, show it, even if you do not understand it. If the program terminates with an operating system error, say which. If nothing at all happens, say so. Even if the result of your test case is a program crash or otherwise obvious it might not happen on our platform. The easiest thing is to copy the output from the terminal, if possible.

Note: If you are reporting an error message, please obtain the most verbose form of the message. In psql, say \set VERBOSITY verbose beforehand. If you are extracting the message from the server log, set the run-time parameter log_error_verbosity to verbose so that all details are logged.

Note: In case of fatal errors, the error message reported by the client might not contain all the information available. Please also look at the log output of the database server. If you do not keep your server’s log output, this would be a good time to start doing so.

- The output you expected is very important to state. If you just write “This command gives me that output.” or “This is not what I expected.”, we might run it ourselves, scan the output, and think it looks OK and is exactly what we expected. We should not have to spend the time to decode the exact semantics behind your commands. Especially refrain from merely saying that “This is not what SQL says/Oracle does.” Digging out the correct behavior from SQL is not a fun undertaking, nor do we all know how all the other relational databases out there behave. (If your problem is a program crash, you can obviously omit this item.)

- Any command line options and other start-up options, including any relevant environment variables or configuration files that you changed from the default. Again, please provide exact information. If you are using a prepackaged distribution that starts the database server at boot time, you should try to find out how that is done.

- Anything you did at all differently from the installation instructions.

- The PostgreSQL version. You can run the command SELECT version(); to find out the version of the server you are connected to. Most executable programs also support a --version option; at least postgres --version and psql --version should work. If the function or the options do not exist then your version is more than old enough to warrant an upgrade. If you run a prepackaged version, such as RPMs, say so, including any subversion the package might have. If you are talking about a Git snapshot, mention that, including the commit hash.
If your version is older than 8.3.23 we will almost certainly tell you to upgrade. There are many bug fixes and improvements in each new release, so it is quite possible that a bug you have encountered in an older release of PostgreSQL has already been fixed. We can only provide limited support for sites using older releases of PostgreSQL; if you require more than we can provide, consider acquiring a commercial support contract.

- Platform information. This includes the kernel name and version, C library, processor, memory information, and so on. In most cases it is sufficient to report the vendor and version, but do not assume everyone knows what exactly “Debian” contains or that everyone runs on Pentiums. If you have installation problems then information about the toolchain on your machine (compiler, make, and so on) is also necessary.

Do not be afraid if your bug report becomes rather lengthy. That is a fact of life. It is better to report everything the first time than us having to squeeze the facts out of you. On the other hand, if your input files are huge, it is fair to ask first whether somebody is interested in looking into it. Here is an article\(^6\) that outlines some more tips on reporting bugs.

Do not spend all your time to figure out which changes in the input make the problem go away. This will probably not help solving it. If it turns out that the bug cannot be fixed right away, you will still have time to find and share your work-around. Also, once again, do not waste your time guessing why the bug exists. We will find that out soon enough.

When writing a bug report, please avoid confusing terminology. The software package in total is called “PostgreSQL”, sometimes “Postgres” for short. If you are specifically talking about the backend server, mention that, do not just say “PostgreSQL crashes”. A crash of a single backend server process is quite different from crash of the parent “postgres” process; please don’t say “the server crashed” when you mean a single backend process went down, nor vice versa. Also, client programs such as the interactive frontend “psql” are completely separate from the backend. Please try to be specific about whether the problem is on the client or server side.

### 5.3. Where to report bugs

In general, send bug reports to the bug report mailing list at <pgsql-bugs@postgresql.org>. You are requested to use a descriptive subject for your email message, perhaps parts of the error message.

Another method is to fill in the bug report web-form available at the project’s web site\(^7\). Entering a bug report this way causes it to be mailed to the <pgsql-bugs@postgresql.org> mailing list.

If your bug report has security implications and you’d prefer that it not become immediately visible in public archives, don’t send it to psql-bugs. Security issues can be reported privately to <security@postgresql.org>.

Do not send bug reports to any of the user mailing lists, such as <pgsql-sql@postgresql.org> or <pgsql-general@postgresql.org>. These mailing lists are for answering user questions, and their subscribers normally do not wish to receive bug reports. More importantly, they are unlikely to fix them.

Also, please do not send reports to the developers’ mailing list <pgsql-hackers@postgresql.org>. This list is for discussing the development of PostgreSQL, and it would be nice if we could keep the bug reports separate. We might choose to take up a discussion about your bug report on psql-hackers, if the problem needs more review.

\(^6\) [http://www.chiark.greenend.org.uk/~sgtatham/bugs.html](http://www.chiark.greenend.org.uk/~sgtatham/bugs.html)

\(^7\) [http://www.postgresql.org/](http://www.postgresql.org/)
If you have a problem with the documentation, the best place to report it is the documentation mailing
list <pgsql-docs@postgresql.org>. Please be specific about what part of the documentation you
are unhappy with.

If your bug is a portability problem on a non-supported platform, send mail to
<pgsql-hackers@postgresql.org>, so we (and you) can work on porting PostgreSQL to your
platform.

**Note:** Due to the unfortunate amount of spam going around, all of the above email addresses
are closed mailing lists. That is, you need to be subscribed to a list to be allowed to post on it.
(You need not be subscribed to use the bug-report web form, however.) If you would like to send
mail but do not want to receive list traffic, you can subscribe and set your subscription option to
nomail. For more information send mail to <majordomo@postgresql.org> with the single word
help in the body of the message.
I. Tutorial

Welcome to the PostgreSQL Tutorial. The following few chapters are intended to give a simple introduction to PostgreSQL, relational database concepts, and the SQL language to those who are new to any one of these aspects. We only assume some general knowledge about how to use computers. No particular Unix or programming experience is required. This part is mainly intended to give you some hands-on experience with important aspects of the PostgreSQL system. It makes no attempt to be a complete or thorough treatment of the topics it covers.

After you have worked through this tutorial you might want to move on to reading Part II to gain a more formal knowledge of the SQL language, or Part IV for information about developing applications for PostgreSQL. Those who set up and manage their own server should also read Part III.
Chapter 1. Getting Started

1.1. Installation

Before you can use PostgreSQL you need to install it, of course. It is possible that PostgreSQL is already installed at your site, either because it was included in your operating system distribution or because the system administrator already installed it. If that is the case, you should obtain information from the operating system documentation or your system administrator about how to access PostgreSQL.

If you are not sure whether PostgreSQL is already available or whether you can use it for your experimentation then you can install it yourself. Doing so is not hard and it can be a good exercise. PostgreSQL can be installed by any unprivileged user; no superuser (root) access is required.

If you are installing PostgreSQL yourself, then refer to Chapter 15 for instructions on installation, and return to this guide when the installation is complete. Be sure to follow closely the section about setting up the appropriate environment variables.

If your site administrator has not set things up in the default way, you might have some more work to do. For example, if the database server machine is a remote machine, you will need to set the PGHOST environment variable to the name of the database server machine. The environment variable PGPORT might also have to be set. The bottom line is this: if you try to start an application program and it complains that it cannot connect to the database, you should consult your site administrator or, if that is you, the documentation to make sure that your environment is properly set up. If you did not understand the preceding paragraph then read the next section.

1.2. Architectural Fundamentals

Before we proceed, you should understand the basic PostgreSQL system architecture. Understanding how the parts of PostgreSQL interact will make this chapter somewhat clearer.

In database jargon, PostgreSQL uses a client/server model. A PostgreSQL session consists of the following cooperating processes (programs):

• A server process, which manages the database files, accepts connections to the database from client applications, and performs actions on the database on behalf of the clients. The database server program is called **postgres**.

• The user’s client (frontend) application that wants to perform database operations. Client applications can be very diverse in nature: a client could be a text-oriented tool, a graphical application, a web server that accesses the database to display web pages, or a specialized database maintenance tool. Some client applications are supplied with the PostgreSQL distribution; most are developed by users.

As is typical of client/server applications, the client and the server can be on different hosts. In that case they communicate over a TCP/IP network connection. You should keep this in mind, because the files that can be accessed on a client machine might not be accessible (or might only be accessible using a different file name) on the database server machine.

The PostgreSQL server can handle multiple concurrent connections from clients. For that purpose it starts (“forks”) a new process for each connection. From that point on, the client and the new
server process communicate without intervention by the original \texttt{postgres} process. Thus, the master server process is always running, waiting for client connections, whereas client and associated server processes come and go. (All of this is of course invisible to the user. We only mention it here for completeness.)

1.3. Creating a Database

The first test to see whether you can access the database server is to try to create a database. A running PostgreSQL server can manage many databases. Typically, a separate database is used for each project or for each user.

Possibly, your site administrator has already created a database for your use. He should have told you what the name of your database is. In that case you can omit this step and skip ahead to the next section.

To create a new database, in this example named \texttt{mydb}, you use the following command:

\$ \texttt{createdb mydb}

If this produces no response then this step was successful and you can skip over the remainder of this section.

If you see a message similar to

\texttt{createdb: command not found}

then PostgreSQL was not installed properly. Either it was not installed at all or the search path was not set correctly. Try calling the command with an absolute path instead:

\$ \texttt{/usr/local/pgsql/bin/createdb mydb}

The path at your site might be different. Contact your site administrator or check back in the installation instructions to correct the situation.

Another response could be this:

\texttt{createdb: could not connect to database postgres: could not connect to server: No such file or directory}

Is the server running locally and accepting connections on Unix domain socket "/tmp/.s.PGSQL.5432"?

This means that the server was not started, or it was not started where \texttt{createdb} expected it. Again, check the installation instructions or consult the administrator.

Another response could be this:

\texttt{createdb: could not connect to database postgres: FATAL: role "joe" does not exist}

where your own login name is mentioned. This will happen if the administrator has not created a PostgreSQL user account for you. (PostgreSQL user accounts are distinct from operating system user accounts.) If you are the administrator, see Chapter 19 for help creating accounts. You will need to become the operating system user under which PostgreSQL was installed (usually \texttt{postgres}) to create the first user account. It could also be that you were assigned a PostgreSQL user name that is different from your operating system user name; in that case you need to use the \texttt{-U} switch or set the \texttt{PGUSER} environment variable to specify your PostgreSQL user name.

If you have a user account but it does not have the privileges required to create a database, you will see the following:
createdb: database creation failed: ERROR: permission denied to create database

Not every user has authorization to create new databases. If PostgreSQL refuses to create databases for you then the site administrator needs to grant you permission to create databases. Consult your site administrator if this occurs. If you installed PostgreSQL yourself then you should log in for the purposes of this tutorial under the user account that you started the server as. ¹

You can also create databases with other names. PostgreSQL allows you to create any number of databases at a given site. Database names must have an alphabetic first character and are limited to 63 bytes in length. A convenient choice is to create a database with the same name as your current user name. Many tools assume that database name as the default, so it can save you some typing. To create that database, simply type

$ createdb

If you do not want to use your database anymore you can remove it. For example, if you are the owner (creator) of the database mydb, you can destroy it using the following command:

$ dropdb mydb

(For this command, the database name does not default to the user account name. You always need to specify it.) This action physically removes all files associated with the database and cannot be undone, so this should only be done with a great deal of forethought.

More about createdb and dropdb can be found in createdb and dropdb respectively.

1.4. Accessing a Database

Once you have created a database, you can access it by:

- Running the PostgreSQL interactive terminal program, called psql, which allows you to interactively enter, edit, and execute SQL commands.
- Using an existing graphical frontend tool like pgAdmin or an office suite with ODBC support to create and manipulate a database. These possibilities are not covered in this tutorial.
- Writing a custom application, using one of the several available language bindings. These possibilities are discussed further in Part IV.

You probably want to start up psql, to try out the examples in this tutorial. It can be activated for the mydb database by typing the command:

$ psql mydb

If you leave off the database name then it will default to your user account name. You already discovered this scheme in the previous section.

In psql, you will be greeted with the following message:

1. As an explanation for why this works: PostgreSQL user names are separate from operating system user accounts. When you connect to a database, you can choose what PostgreSQL user name to connect as; if you don’t, it will default to the same name as your current operating system account. As it happens, there will always be a PostgreSQL user account that has the same name as the operating system user that started the server, and it also happens that that user always has permission to create databases. Instead of logging in as that user you can also specify the –U option everywhere to select a PostgreSQL user name to connect as.
Welcome to psql 8.3.23, the PostgreSQL interactive terminal.

Type: \copyright for distribution terms
\h for help with SQL commands
? for help with psql commands
\g or terminate with semicolon to execute query
\q to quit

mydb=>

The last line could also be

mydb=#

That would mean you are a database superuser, which is most likely the case if you installed PostgreSQL yourself. Being a superuser means that you are not subject to access controls. For the purposes of this tutorial that is not of importance.

If you encounter problems starting psql then go back to the previous section. The diagnostics of createdb and psql are similar, and if the former worked the latter should work as well.

The last line printed out by psql is the prompt, and it indicates that psql is listening to you and that you can type SQL queries into a work space maintained by psql. Try out these commands:

mydb=> SELECT version();

```
version
-----------------------------------------------------
PostgreSQL 8.3.23 on i586-pc-linux-gnu, compiled by GCC 2.96
(1 row)
```

mydb=> SELECT current_date;

date
------
2002-08-31
(1 row)

mydb=> SELECT 2 + 2;?

```
?column?
-------
4
(1 row)
```

The psql program has a number of internal commands that are not SQL commands. They begin with the backslash character, "\". Some of these commands were listed in the welcome message. For example, you can get help on the syntax of various PostgreSQL SQL commands by typing:

mydb=> \h

To get out of psql, type

mydb=> \q

and psql will quit and return you to your command shell. (For more internal commands, type \? at the psql prompt.) The full capabilities of psql are documented in psql. If PostgreSQL is installed correctly you can also type man psql at the operating system shell prompt to see the documentation.
In this tutorial we will not use these features explicitly, but you can use them yourself when you see fit.
Chapter 2. The SQL Language

2.1. Introduction

This chapter provides an overview of how to use SQL to perform simple operations. This tutorial is only intended to give you an introduction and is in no way a complete tutorial on SQL. Numerous books have been written on SQL, including *Understanding the New SQL* and *A Guide to the SQL Standard*. You should be aware that some PostgreSQL language features are extensions to the standard.

In the examples that follow, we assume that you have created a database named `mydb`, as described in the previous chapter, and have been able to start `psql`.

Examples in this manual can also be found in the PostgreSQL source distribution in the directory `src/tutorial/`. To use those files, first change to that directory and run make:

```bash
$ cd ....~/src/tutorial
$ make
```

This creates the scripts and compiles the C files containing user-defined functions and types. (If you installed a pre-packaged version of PostgreSQL rather than building from source, look for a directory named `tutorial` within the PostgreSQL documentation. The “make” part should already have been done for you.) Then, to start the tutorial, do the following:

```bash
$ cd ....~/tutorial
$ psql -s mydb
...

mydb=> \i basics.sql
```

The `\i` command reads in commands from the specified file. The `-s` option puts you in single step mode which pauses before sending each statement to the server. The commands used in this section are in the file `basics.sql`.

2.2. Concepts

PostgreSQL is a *relational database management system* (RDBMS). That means it is a system for managing data stored in *relations*. Relation is essentially a mathematical term for *table*. The notion of storing data in tables is so commonplace today that it might seem inherently obvious, but there are a number of other ways of organizing databases. Files and directories on Unix-like operating systems form an example of a hierarchical database. A more modern development is the object-oriented database.

Each table is a named collection of *rows*. Each row of a given table has the same set of named *columns*, and each column is of a specific data type. Whereas columns have a fixed order in each row, it is important to remember that SQL does not guarantee the order of the rows within the table in any way (although they can be explicitly sorted for display).

Tables are grouped into databases, and a collection of databases managed by a single PostgreSQL server instance constitutes a database *cluster*. 
2.3. Creating a New Table

You can create a new table by specifying the table name, along with all column names and their types:

```
CREATE TABLE weather (  
city varchar(80), 
temp_lo int, -- low temperature 
temp_hi int, -- high temperature 
prcp real, -- precipitation 
date date
);
```

You can enter this into `psql` with the line breaks. `psql` will recognize that the command is not terminated until the semicolon.

White space (i.e., spaces, tabs, and newlines) can be used freely in SQL commands. That means you can type the command aligned differently than above, or even all on one line. Two dashes ("--") introduce comments. Whatever follows them is ignored up to the end of the line. SQL is case insensitive about key words and identifiers, except when identifiers are double-quoted to preserve the case (not done above).

`varchar(80)` specifies a data type that can store arbitrary character strings up to 80 characters in length. `int` is the normal integer type. `real` is a type for storing single precision floating-point numbers. `date` should be self-explanatory. (Yes, the column of type `date` is also named `date`. This might be convenient or confusing — you choose.)

PostgreSQL supports the standard SQL types `int`, `smallint`, `real`, `double precision`, `char(N)`, `varchar(N)`, `date`, `time`, `timestamp`, and `interval`, as well as other types of general utility and a rich set of geometric types. PostgreSQL can be customized with an arbitrary number of user-defined data types. Consequently, type names are not syntactical key words, except where required to support special cases in the SQL standard.

The second example will store cities and their associated geographical location:

```
CREATE TABLE cities (  
  name varchar(80),  
  location point
);
```

The `point` type is an example of a PostgreSQL-specific data type.

Finally, it should be mentioned that if you don’t need a table any longer or want to recreate it differently you can remove it using the following command:

```
DROP TABLE tablename;
```

2.4. Populating a Table With Rows

The `INSERT` statement is used to populate a table with rows:

```
INSERT INTO weather VALUES ('San Francisco', 46, 50, 0.25, '1994-11-27');
```
Note that all data types use rather obvious input formats. Constants that are not simple numeric values usually must be surrounded by single quotes (‘’), as in the example. The date type is actually quite flexible in what it accepts, but for this tutorial we will stick to the unambiguous format shown here.

The point type requires a coordinate pair as input, as shown here:

```
INSERT INTO cities VALUES ('San Francisco', '(-194.0, 53.0)');
```

The syntax used so far requires you to remember the order of the columns. An alternative syntax allows you to list the columns explicitly:

```
INSERT INTO weather (city, temp_lo, temp_hi, prcp, date)
    VALUES ('San Francisco', 43, 57, 0.0, '1994-11-29');
```

You can list the columns in a different order if you wish or even omit some columns, e.g., if the precipitation is unknown:

```
INSERT INTO weather (date, city, temp_hi, temp_lo)
    VALUES ('1994-11-29', 'Hayward', 54, 37);
```

Many developers consider explicitly listing the columns better style than relying on the order implicitly.

Please enter all the commands shown above so you have some data to work with in the following sections.

You could also have used COPY to load large amounts of data from flat-text files. This is usually faster because the COPY command is optimized for this application while allowing less flexibility than INSERT. An example would be:

```
COPY weather FROM '/home/user/weather.txt';
```

where the file name for the source file must be available to the backend server machine, not the client, since the backend server reads the file directly. You can read more about the COPY command in COPY.

### 2.5. Querying a Table

To retrieve data from a table, the table is queried. An SQL SELECT statement is used to do this. The statement is divided into a select list (the part that lists the columns to be returned), a table list (the part that lists the tables from which to retrieve the data), and an optional qualification (the part that specifies any restrictions). For example, to retrieve all the rows of table weather, type:

```
SELECT * FROM weather;
```

Here * is a shorthand for “all columns”. So the same result would be had with:

```
SELECT city, temp_lo, temp_hi, prcp, date FROM weather;
```

The output should be:

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
</table>

1. While SELECT * is useful for off-the-cuff queries, it is widely considered bad style in production code, since adding a column to the table would change the results.
You can write expressions, not just simple column references, in the select list. For example, you can do:

```
SELECT city, (temp_hi+temp_lo)/2 AS temp_avg, date FROM weather;
```

This should give:

<table>
<thead>
<tr>
<th>city</th>
<th>temp_avg</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>48</td>
<td>1994-11-27</td>
</tr>
<tr>
<td>San Francisco</td>
<td>50</td>
<td>1994-11-29</td>
</tr>
<tr>
<td>Hayward</td>
<td>45</td>
<td>1994-11-29</td>
</tr>
</tbody>
</table>

(3 rows)

Notice how the AS clause is used to relabel the output column. (The AS clause is optional.)

A query can be "qualified" by adding a WHERE clause that specifies which rows are wanted. The WHERE clause contains a Boolean (truth value) expression, and only rows for which the Boolean expression is true are returned. The usual Boolean operators (AND, OR, and NOT) are allowed in the qualification. For example, the following retrieves the weather of San Francisco on rainy days:

```
SELECT * FROM weather
WHERE city = 'San Francisco' AND prcp > 0.0;
```

Result:

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
</tbody>
</table>

(1 row)

You can request that the results of a query be returned in sorted order:

```
SELECT * FROM weather
ORDER BY city;
```

```
<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
<td>37</td>
<td>54</td>
<td></td>
<td>1994-11-29</td>
</tr>
<tr>
<td>San Francisco</td>
<td>43</td>
<td>57</td>
<td>0</td>
<td>1994-11-29</td>
</tr>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
</tbody>
</table>
```

In this example, the sort order isn’t fully specified, and so you might get the San Francisco rows in either order. But you’d always get the results shown above if you do:

```
SELECT * FROM weather
ORDER BY city, temp_lo;
```

You can request that duplicate rows be removed from the result of a query:
SELECT DISTINCT city
FROM weather;

city
---------------
Hayward
San Francisco
(2 rows)

Here again, the result row ordering might vary. You can ensure consistent results by using `DISTINCT` and `ORDER BY` together:

```sql
SELECT DISTINCT city
FROM weather
ORDER BY city;
```

### 2.6. Joins Between Tables

Thus far, our queries have only accessed one table at a time. Queries can access multiple tables at once, or access the same table in such a way that multiple rows of the table are being processed at the same time. A query that accesses multiple rows of the same or different tables at one time is called a *join* query. As an example, say you wish to list all the weather records together with the location of the associated city. To do that, we need to compare the city column of each row of the weather table with the name column of all rows in the cities table, and select the pairs of rows where these values match.

**Note:** This is only a conceptual model. The join is usually performed in a more efficient manner than actually comparing each possible pair of rows, but this is invisible to the user.

This would be accomplished by the following query:

```sql
SELECT *
FROM weather, cities
WHERE city = name;
```

city | temp_lo | temp_hi | prcp | date | name | location
---------------+---------+---------+------|------------+---------------+-----------
San Francisco | 46 | 50 | 0.25 | 1994-11-27 | San Francisco | (-194,53)
San Francisco | 43 | 57 | 0 | 1994-11-29 | San Francisco | (-194,53)
(2 rows)

Observe two things about the result set:

- There is no result row for the city of Hayward. This is because there is no matching entry in the `cities` table for Hayward, so the join ignores the unmatched rows in the weather table. We will see shortly how this can be fixed.

---

2. In some database systems, including older versions of PostgreSQL, the implementation of `DISTINCT` automatically orders the rows and so `ORDER BY` is unnecessary. But this is not required by the SQL standard, and current PostgreSQL doesn’t guarantee that `DISTINCT` causes the rows to be ordered.
There are two columns containing the city name. This is correct because the lists of columns of the `weather` and the `cities` table are concatenated. In practice this is undesirable, though, so you will probably want to list the output columns explicitly rather than using `*`

```sql
SELECT city, temp_lo, temp_hi, prcp, date, location
FROM weather, cities
WHERE city = name;
```

**Exercise:** Attempt to find out the semantics of this query when the `WHERE` clause is omitted.

Since the columns all had different names, the parser automatically found out which table they belong to. If there were duplicate column names in the two tables you’d need to qualify the column names to show which one you meant, as in:

```sql
SELECT weather.city, weather.temp_lo, weather.temp_hi,
       weather.prcp, weather.date, cities.location
FROM weather, cities
WHERE cities.name = weather.city;
```

It is widely considered good style to qualify all column names in a join query, so that the query won’t fail if a duplicate column name is later added to one of the tables.

Join queries of the kind seen thus far can also be written in this alternative form:

```sql
SELECT *
FROM weather INNER JOIN cities ON (weather.city = cities.name);
```

This syntax is not as commonly used as the one above, but we show it here to help you understand the following topics.

Now we will figure out how we can get the Hayward records back in. What we want the query to do is to scan the `weather` table and for each row to find the matching `cities` row(s). If no matching row is found we want some “empty values” to be substituted for the `cities` table’s columns. This kind of query is called an outer join. (The joins we have seen so far are inner joins.) The command looks like this:

```sql
SELECT *
FROM weather LEFT OUTER JOIN cities ON (weather.city = cities.name);
```

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
<th>name</th>
<th>location</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
<td>37</td>
<td>54</td>
<td></td>
<td>1994-11-29</td>
<td></td>
<td></td>
</tr>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
<td>San Francisco</td>
<td>(-194,53)</td>
</tr>
<tr>
<td>San Francisco</td>
<td>43</td>
<td>57</td>
<td>0</td>
<td>1994-11-29</td>
<td>San Francisco</td>
<td>(-194,53)</td>
</tr>
</tbody>
</table>

(3 rows)

This query is called a left outer join because the table mentioned on the left of the join operator will have each of its rows in the output at least once, whereas the table on the right will only have those rows output that match some row of the left table. When outputting a left-table row for which there is no right-table match, empty (null) values are substituted for the right-table columns.

**Exercise:** There are also right outer joins and full outer joins. Try to find out what those do.

We can also join a table against itself. This is called a self join. As an example, suppose we wish to find all the weather records that are in the temperature range of other weather records. So we need to compare the `temp_lo` and `temp_hi` columns of each `weather` row to the `temp_lo` and `temp_hi` columns of all other `weather` rows. We can do this with the following query:

```sql
11
```
Chapter 2. The SQL Language

SELECT W1.city, W1.temp_lo AS low, W1.temp_hi AS high,
     W2.city, W2.temp_lo AS low, W2.temp_hi AS high
FROM weather W1, weather W2
WHERE W1.temp_lo < W2.temp_lo
     AND W1.temp_hi > W2.temp_hi;

<table>
<thead>
<tr>
<th>city</th>
<th>low</th>
<th>high</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>43</td>
<td>57</td>
</tr>
<tr>
<td>Hayward</td>
<td>37</td>
<td>54</td>
</tr>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
</tr>
</tbody>
</table>

(2 rows)

Here we have relabeled the weather table as W1 and W2 to be able to distinguish the left and right side of the join. You can also use these kinds of aliases in other queries to save some typing, e.g.:

SELECT *
     FROM weather w, cities c
     WHERE w.city = c.name;

You will encounter this style of abbreviating quite frequently.

2.7. Aggregate Functions

Like most other relational database products, PostgreSQL supports aggregate functions. An aggregate function computes a single result from multiple input rows. For example, there are aggregates to compute the count, sum, avg (average), max (maximum) and min (minimum) over a set of rows.

As an example, we can find the highest low-temperature reading anywhere with:

SELECT max(temp_lo) FROM weather;

<table>
<thead>
<tr>
<th>max</th>
</tr>
</thead>
<tbody>
<tr>
<td>46</td>
</tr>
</tbody>
</table>

(1 row)

If we wanted to know what city (or cities) that reading occurred in, we might try:

SELECT city FROM weather WHERE temp_lo = max(temp_lo);  WRONG

but this will not work since the aggregate max cannot be used in the WHERE clause. (This restriction exists because the WHERE clause determines which rows will be included in the aggregate calculation; so obviously it has to be evaluated before aggregate functions are computed.) However, as is often the case the query can be restated to accomplish the desired result, here by using a subquery:

SELECT city FROM weather
     WHERE temp_lo = (SELECT max(temp_lo) FROM weather);

<table>
<thead>
<tr>
<th>city</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
</tr>
</tbody>
</table>

(1 row)
This is OK because the subquery is an independent computation that computes its own aggregate separately from what is happening in the outer query.

Aggregates are also very useful in combination with GROUP BY clauses. For example, we can get the maximum low temperature observed in each city with:

```sql
SELECT city, max(temp_lo)  
FROM weather  
GROUP BY city;
```

<table>
<thead>
<tr>
<th>city</th>
<th>max</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
<td>37</td>
</tr>
<tr>
<td>San Francisco</td>
<td>46</td>
</tr>
</tbody>
</table>

(2 rows)

which gives us one output row per city. Each aggregate result is computed over the table rows matching that city. We can filter these grouped rows using HAVING:

```sql
SELECT city, max(temp_lo)  
FROM weather  
GROUP BY city  
HAVING max(temp_lo) < 40;
```

<table>
<thead>
<tr>
<th>city</th>
<th>max</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
<td>37</td>
</tr>
</tbody>
</table>

(1 row)

which gives us the same results for only the cities that have all temp_lo values below 40. Finally, if we only care about cities whose names begin with “S”, we might do:

```sql
SELECT city, max(temp_lo)  
FROM weather  
WHERE city LIKE 'S%'  
GROUP BY city  
HAVING max(temp_lo) < 40;
```

The LIKE operator does pattern matching and is explained in Section 9.7.

It is important to understand the interaction between aggregates and SQL’s WHERE and HAVING clauses. The fundamental difference between WHERE and HAVING is this: WHERE selects input rows before groups and aggregates are computed (thus, it controls which rows go into the aggregate computation), whereas HAVING selects group rows after groups and aggregates are computed. Thus, the WHERE clause must not contain aggregate functions; it makes no sense to try to use an aggregate to determine which rows will be inputs to the aggregates. On the other hand, the HAVING clause always contains aggregate functions. (Strictly speaking, you are allowed to write a HAVING clause that doesn’t use aggregates, but it’s seldom useful. The same condition could be used more efficiently at the WHERE stage.)

In the previous example, we can apply the city name restriction in WHERE, since it needs no aggregate. This is more efficient than adding the restriction to HAVING, because we avoid doing the grouping and aggregate calculations for all rows that fail the WHERE check.
2.8. Updates

You can update existing rows using the UPDATE command. Suppose you discover the temperature readings are all off by 2 degrees after November 28. You can correct the data as follows:

```
UPDATE weather
    SET temp_hi = temp_hi - 2, temp_lo = temp_lo - 2
    WHERE date > '1994-11-28';
```

Look at the new state of the data:

```
SELECT * FROM weather;
```

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
<tr>
<td>San Francisco</td>
<td>41</td>
<td>55</td>
<td>0</td>
<td>1994-11-29</td>
</tr>
<tr>
<td>Hayward</td>
<td>35</td>
<td>52</td>
<td></td>
<td>1994-11-29</td>
</tr>
</tbody>
</table>

(3 rows)

2.9. Deletions

Rows can be removed from a table using the DELETE command. Suppose you are no longer interested in the weather of Hayward. Then you can do the following to delete those rows from the table:

```
DELETE FROM weather WHERE city = 'Hayward';
```

All weather records belonging to Hayward are removed.

```
SELECT * FROM weather;
```

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
<tr>
<td>San Francisco</td>
<td>41</td>
<td>55</td>
<td>0</td>
<td>1994-11-29</td>
</tr>
</tbody>
</table>

(2 rows)

One should be wary of statements of the form

```
DELETE FROM tablename;
```

Without a qualification, DELETE will remove all rows from the given table, leaving it empty. The system will not request confirmation before doing this!
Chapter 3. Advanced Features

3.1. Introduction

In the previous chapter we have covered the basics of using SQL to store and access your data in PostgreSQL. We will now discuss some more advanced features of SQL that simplify management and prevent loss or corruption of your data. Finally, we will look at some PostgreSQL extensions.

This chapter will on occasion refer to examples found in Chapter 2 to change or improve them, so it will be of advantage if you have read that chapter. Some examples from this chapter can also be found in advanced.sql in the tutorial directory. This file also contains some example data to load, which is not repeated here. (Refer to Section 2.1 for how to use the file.)

3.2. Views

Refer back to the queries in Section 2.6. Suppose the combined listing of weather records and city location is of particular interest to your application, but you do not want to type the query each time you need it. You can create a view over the query, which gives a name to the query that you can refer to like an ordinary table:

```sql
CREATE VIEW myview AS
    SELECT city, temp_lo, temp_hi, prcp, date, location
    FROM weather, cities
    WHERE city = name;

SELECT * FROM myview;
```

Making liberal use of views is a key aspect of good SQL database design. Views allow you to encapsulate the details of the structure of your tables, which might change as your application evolves, behind consistent interfaces.

Views can be used in almost any place a real table can be used. Building views upon other views is not uncommon.

3.3. Foreign Keys

Recall the weather and cities tables from Chapter 2. Consider the following problem: You want to make sure that no one can insert rows in the weather table that do not have a matching entry in the cities table. This is called maintaining the referential integrity of your data. In simplistic database systems this would be implemented (if at all) by first looking at the cities table to check if a matching record exists, and then inserting or rejecting the new weather records. This approach has a number of problems and is very inconvenient, so PostgreSQL can do this for you.

The new declaration of the tables would look like this:

```sql
CREATE TABLE cities {
    city varchar(80) primary key,
    location point
};
```
CREATE TABLE weather (  
city   varchar(80) references cities(city),
temp_lo int,
temp_hi int,
prcp   real,
date   date
);

Now try inserting an invalid record:

INSERT INTO weather VALUES ('Berkeley', 45, 53, 0.0, '1994-11-28');

ERROR: insert or update on table "weather" violates foreign key constraint "weather_city_fkey"
DETAIL: Key (city)=(Berkeley) is not present in table "cities".

The behavior of foreign keys can be finely tuned to your application. We will not go beyond this simple example in this tutorial, but just refer you to Chapter 5 for more information. Making correct use of foreign keys will definitely improve the quality of your database applications, so you are strongly encouraged to learn about them.

3.4. Transactions

Transactions are a fundamental concept of all database systems. The essential point of a transaction is that it bundles multiple steps into a single, all-or-nothing operation. The intermediate states between the steps are not visible to other concurrent transactions, and if some failure occurs that prevents the transaction from completing, then none of the steps affect the database at all.

For example, consider a bank database that contains balances for various customer accounts, as well as total deposit balances for branches. Suppose that we want to record a payment of $100.00 from Alice’s account to Bob’s account. Simplifying outrageously, the SQL commands for this might look like:

```
UPDATE accounts SET balance = balance - 100.00
   WHERE name = 'Alice';
UPDATE branches SET balance = balance - 100.00
   WHERE name = (SELECT branch_name FROM accounts WHERE name = 'Alice');
UPDATE accounts SET balance = balance + 100.00
   WHERE name = 'Bob';
UPDATE branches SET balance = balance + 100.00
   WHERE name = (SELECT branch_name FROM accounts WHERE name = 'Bob');
```

The details of these commands are not important here; the important point is that there are several separate updates involved to accomplish this rather simple operation. Our bank’s officers will want to be assured that either all these updates happen, or none of them happen. It would certainly not do for a system failure to result in Bob receiving $100.00 that was not debited from Alice. Nor would Alice long remain a happy customer if she was debited without Bob being credited. We need a guarantee that if something goes wrong partway through the operation, none of the steps executed so far will take effect. Grouping the updates into a transaction gives us this guarantee. A transaction is said to be atomic: from the point of view of other transactions, it either happens completely or not at all.
Chapter 3. Advanced Features

We also want a guarantee that once a transaction is completed and acknowledged by the database system, it has indeed been permanently recorded and won’t be lost even if a crash ensues shortly thereafter. For example, if we are recording a cash withdrawal by Bob, we do not want any chance that the debit to his account will disappear in a crash just after he walks out the bank door. A transactional database guarantees that all the updates made by a transaction are logged in permanent storage (i.e., on disk) before the transaction is reported complete.

Another important property of transactional databases is closely related to the notion of atomic updates: when multiple transactions are running concurrently, each one should not be able to see the incomplete changes made by others. For example, if one transaction is busy totalling all the branch balances, it would not do for it to include the debit from Alice’s branch but not the credit to Bob’s branch, nor vice versa. So transactions must be all-or-nothing not only in terms of their permanent effect on the database, but also in terms of their visibility as they happen. The updates made so far by an open transaction are invisible to other transactions until the transaction completes, whereupon all the updates become visible simultaneously.

In PostgreSQL, a transaction is set up by surrounding the SQL commands of the transaction with \texttt{BEGIN} and \texttt{COMMIT} commands. So our banking transaction would actually look like:

\begin{verbatim}
BEGIN;
UPDATE accounts SET balance = balance - 100.00
   WHERE name = 'Alice';
-- etc etc
COMMIT;
\end{verbatim}

If, partway through the transaction, we decide we do not want to commit (perhaps we just noticed that Alice’s balance went negative), we can issue the command \texttt{ROLLBACK} instead of \texttt{COMMIT}, and all our updates so far will be canceled.

PostgreSQL actually treats every SQL statement as being executed within a transaction. If you do not issue a \texttt{BEGIN} command, then each individual statement has an implicit \texttt{BEGIN} and (if successful) \texttt{COMMIT} wrapped around it. A group of statements surrounded by \texttt{BEGIN} and \texttt{COMMIT} is sometimes called a transaction block.

\textbf{Note:} Some client libraries issue \texttt{BEGIN} and \texttt{COMMIT} commands automatically, so that you might get the effect of transaction blocks without asking. Check the documentation for the interface you are using.

It’s possible to control the statements in a transaction in a more granular fashion through the use of \texttt{savepoints}. Savepoints allow you to selectively discard parts of the transaction, while committing the rest. After defining a savepoint with \texttt{SAVEPOINT}, you can if needed roll back to the savepoint with \texttt{ROLLBACK TO}. All the transaction’s database changes between defining the savepoint and rolling back to it are discarded, but changes earlier than the savepoint are kept.

After rolling back to a savepoint, it continues to be defined, so you can roll back to it several times. Conversely, if you are sure you won’t need to roll back to a particular savepoint again, it can be released, so the system can free some resources. Keep in mind that either releasing or rolling back to a savepoint will automatically release all savepoints that were defined after it.

All this is happening within the transaction block, so none of it is visible to other database sessions. When and if you commit the transaction block, the committed actions become visible as a unit to other sessions, while the rolled-back actions never become visible at all.
Remembering the bank database, suppose we debit $100.00 from Alice’s account, and credit Bob’s account, only to find later that we should have credited Wally’s account. We could do it using savepoints like this:

```
BEGIN;
UPDATE accounts SET balance = balance - 100.00
   WHERE name = 'Alice';
SAVEPOINT my_savepoint;
UPDATE accounts SET balance = balance + 100.00
   WHERE name = 'Bob';
-- oops ... forget that and use Wally’s account
ROLLBACK TO my_savepoint;
UPDATE accounts SET balance = balance + 100.00
   WHERE name = 'Wally';
COMMIT;
```

This example is, of course, oversimplified, but there’s a lot of control to be had over a transaction block through the use of savepoints. Moreover, ROLLBACK TO is the only way to regain control of a transaction block that was put in aborted state by the system due to an error, short of rolling it back completely and starting again.

### 3.5. Inheritance

Inheritance is a concept from object-oriented databases. It opens up interesting new possibilities of database design.

Let’s create two tables: A table `cities` and a table `capitals`. Naturally, capitals are also cities, so you want some way to show the capitals implicitly when you list all cities. If you’re really clever you might invent some scheme like this:

```
CREATE TABLE capitals (
   name text,
   population real,
   altitude int,     -- (in ft)
   state char(2)
);

CREATE TABLE non_capitals (
   name text,
   population real,
   altitude int -- (in ft)
);

CREATE VIEW cities AS
   SELECT name, population, altitude FROM capitals
UNION
   SELECT name, population, altitude FROM non_capitals;
```

This works OK as far as querying goes, but it gets ugly when you need to update several rows, for one thing.

A better solution is this:

```
CREATE TABLE cities (
   name text,
   population real,
   altitude int -- (in ft)
);
```
In this case, a row of capitals inherits all columns (name, population, and altitude) from its parent, cities. The type of the column name is text, a native PostgreSQL type for variable length character strings. State capitals have an extra column, state, that shows their state. In PostgreSQL, a table can inherit from zero or more other tables.

For example, the following query finds the names of all cities, including state capitals, that are located at an altitude over 500 feet:

```sql
SELECT name, altitude
FROM cities
WHERE altitude > 500;
```

which returns:

<table>
<thead>
<tr>
<th>name</th>
<th>altitude</th>
</tr>
</thead>
<tbody>
<tr>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>Mariposa</td>
<td>1953</td>
</tr>
<tr>
<td>Madison</td>
<td>845</td>
</tr>
</tbody>
</table>

(3 rows)

On the other hand, the following query finds all the cities that are not state capitals and are situated at an altitude of 500 feet or higher:

```sql
SELECT name, altitude
FROM ONLY cities
WHERE altitude > 500;
```

which returns:

<table>
<thead>
<tr>
<th>name</th>
<th>altitude</th>
</tr>
</thead>
<tbody>
<tr>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>Mariposa</td>
<td>1953</td>
</tr>
</tbody>
</table>

(2 rows)

Here the ONLY before cities indicates that the query should be run over only the cities table, and not tables below cities in the inheritance hierarchy. Many of the commands that we have already discussed — SELECT, UPDATE, and DELETE — support this ONLY notation.

**Note:** Although inheritance is frequently useful, it has not been integrated with unique constraints or foreign keys, which limits its usefulness. See Section 5.8 for more detail.
3.6. Conclusion

PostgreSQL has many features not touched upon in this tutorial introduction, which has been oriented toward newer users of SQL. These features are discussed in more detail in the remainder of this book. If you feel you need more introductory material, please visit the PostgreSQL web site\(^1\) for links to more resources.

\(^1\) http://www.postgresql.org
II. The SQL Language

This part describes the use of the SQL language in PostgreSQL. We start with describing the general syntax of SQL, then explain how to create the structures to hold data, how to populate the database, and how to query it. The middle part lists the available data types and functions for use in SQL commands. The rest treats several aspects that are important for tuning a database for optimal performance.

The information in this part is arranged so that a novice user can follow it start to end to gain a full understanding of the topics without having to refer forward too many times. The chapters are intended to be self-contained, so that advanced users can read the chapters individually as they choose. The information in this part is presented in a narrative fashion in topical units. Readers looking for a complete description of a particular command should look into Part VI.

Readers of this part should know how to connect to a PostgreSQL database and issue SQL commands. Readers that are unfamiliar with these issues are encouraged to read Part I first. SQL commands are typically entered using the PostgreSQL interactive terminal psql, but other programs that have similar functionality can be used as well.
Chapter 4. SQL Syntax

This chapter describes the syntax of SQL. It forms the foundation for understanding the following chapters which will go into detail about how the SQL commands are applied to define and modify data.

We also advise users who are already familiar with SQL to read this chapter carefully because there are several rules and concepts that are implemented inconsistently among SQL databases or that are specific to PostgreSQL.

4.1. Lexical Structure

SQL input consists of a sequence of commands. A command is composed of a sequence of tokens, terminated by a semicolon ";". The end of the input stream also terminates a command. Which tokens are valid depends on the syntax of the particular command.

A token can be a key word, an identifier, a quoted identifier, a literal (or constant), or a special character symbol. Tokens are normally separated by whitespace (space, tab, newline), but need not be if there is no ambiguity (which is generally only the case if a special character is adjacent to some other token type).

Additionally, comments can occur in SQL input. They are not tokens, they are effectively equivalent to whitespace.

For example, the following is (syntactically) valid SQL input:

```
SELECT * FROM MY_TABLE;
UPDATE MY_TABLE SET A = 5;
INSERT INTO MY_TABLE VALUES (3, 'hi there');
```

This is a sequence of three commands, one per line (although this is not required; more than one command can be on a line, and commands can usefully be split across lines).

The SQL syntax is not very consistent regarding what tokens identify commands and which are operands or parameters. The first few tokens are generally the command name, so in the above example we would usually speak of a “SELECT”, an “UPDATE”, and an “INSERT” command. But for instance the UPDATE command always requires a SET token to appear in a certain position, and this particular variation of INSERT also requires a VALUES in order to be complete. The precise syntax rules for each command are described in Part VI.

4.1.1. Identifiers and Key Words

Tokens such as SELECT, UPDATE, or VALUES in the example above are examples of key words, that is, words that have a fixed meaning in the SQL language. The tokens MY_TABLE and A are examples of identifiers. They identify names of tables, columns, or other database objects, depending on the command they are used in. Therefore they are sometimes simply called “names”. Key words and identifiers have the same lexical structure, meaning that one cannot know whether a token is an identifier or a key word without knowing the language. A complete list of key words can be found in Appendix C.

SQL identifiers and key words must begin with a letter (a-z, but also letters with diacritical marks and non-Latin letters) or an underscore (_). Subsequent characters in an identifier or key word can be letters, underscores, digits (0-9), or dollar signs ($). Note that dollar signs are not allowed in identifiers according to the letter of the SQL standard, so their use might render applications less portable. The
Chapter 4. SQL Syntax

SQL standard will not define a key word that contains digits or starts or ends with an underscore, so identifiers of this form are safe against possible conflict with future extensions of the standard.

The system uses no more than NAMEDATALEN-1 bytes of an identifier; longer names can be written in commands, but they will be truncated. By default, NAMEDATALEN is 64 so the maximum identifier length is 63 bytes. If this limit is problematic, it can be raised by changing the NAMEDATALEN constant in src/include/pg_config_manual.h.

Identifier and key word names are case insensitive. Therefore:

```
UPDATE MY_TABLE SET A = 5;
```

can equivalently be written as:

```
uPDaTE my_TabLE SeT a = 5;
```

A convention often used is to write key words in upper case and names in lower case, e.g.:

```
UPDATE my_table SET a = 5;
```

There is a second kind of identifier: the delimited identifier or quoted identifier. It is formed by enclosing an arbitrary sequence of characters in double-quotes ("). A delimited identifier is always an identifier, never a key word. So *select* could be used to refer to a column or table named "select", whereas an unquoted select would be taken as a key word and would therefore provoke a parse error when used where a table or column name is expected. The example can be written with quoted identifiers like this:

```
UPDATE "my_table" SET "a" = 5;
```

Quoted identifiers can contain any character, except the character with code zero. (To include a double quote, write two double quotes.) This allows constructing table or column names that would otherwise not be possible, such as ones containing spaces or ampersands. The length limitation still applies.

Quoting an identifier also makes it case-sensitive, whereas unquoted names are always folded to lower case. For example, the identifiers FOO, foo, and "foo" are considered the same by PostgreSQL, but "Foo" and "FOO" are different from these three and each other. (The folding of unquoted names to lower case in PostgreSQL is incompatible with the SQL standard, which says that unquoted names should be folded to upper case. Thus, foo should be equivalent to "FOO" not "foo" according to the standard. If you want to write portable applications you are advised to always quote a particular name or never quote it.)

4.1.2. Constants

There are three kinds of implicitly-typed constants in PostgreSQL: strings, bit strings, and numbers. Constants can also be specified with explicit types, which can enable more accurate representation and more efficient handling by the system. These alternatives are discussed in the following subsections.

4.1.2.1. String Constants

A string constant in SQL is an arbitrary sequence of characters bounded by single quotes (’), for example ‘This is a string’. To include a single-quote character within a string constant, write
two adjacent single quotes, e.g. ‘Dianne’s horse’. Note that this is not the same as a double-quote character (").

Two string constants that are only separated by whitespace with at least one newline are concatenated and effectively treated as if the string had been written as one constant. For example:

```sql
SELECT 'foo'
 'bar';
```

is equivalent to:

```sql
SELECT 'foobar';
```

but:

```sql
SELECT 'foo' 'bar';
```

is not valid syntax. (This slightly bizarre behavior is specified by SQL; PostgreSQL is following the standard.)

PostgreSQL also accepts “escape” string constants, which are an extension to the SQL standard. An escape string constant is specified by writing the letter E (upper or lower case) just before the opening single quote, e.g. E’foo’. (When continuing an escape string constant across lines, write E only before the first opening quote.) Within an escape string, a backslash character (\) begins a C-like \_backslash escape sequence, in which the combination of backslash and following character(s) represents a special byte value. \b is a backspace, \f is a form feed, \n is a newline, \r is a carriage return, \t is a tab. Also supported are \_digits, where \_digits represents an octal byte value, and \_hexdigits, where \_hexdigits represents a hexadecimal byte value. (It is your responsibility that the byte sequences you create are valid characters in the server character set encoding.) Any other character following a backslash is taken literally. Thus, to include a backslash character, write two backslashes (\\). Also, a single quote can be included in an escape string by writing \\\', in addition to the normal way of ‘.

<table>
<thead>
<tr>
<th>Caution</th>
</tr>
</thead>
<tbody>
<tr>
<td>If the configuration parameter standard_conforming_strings is off, then PostgreSQL recognizes backslash escapes in both regular and escape string constants. This is for backward compatibility with the historical behavior, in which backslash escapes were always recognized. Although standard_conforming_strings currently defaults to off, the default will change to on in a future release for improved standards compliance. Applications are therefore encouraged to migrate away from using backslash escapes. If you need to use a backslash escape to represent a special character, write the constant with an E to be sure it will be handled the same way in future releases. In addition to standard_conforming_strings, the configuration parameters escape_string_warning and backslash_quote govern treatment of backslashes in string constants.</td>
</tr>
</tbody>
</table>

The character with the code zero cannot be in a string constant.

### 4.1.2.2. Dollar-Quoted String Constants

While the standard syntax for specifying string constants is usually convenient, it can be difficult to understand when the desired string contains many single quotes or backslashes, since each of those
must be doubled. To allow more readable queries in such situations, PostgreSQL provides another
way, called “dollar quoting”, to write string constants. A dollar-quoted string constant consists of a
dollar sign ($), an optional “tag” of zero or more characters, another dollar sign, an arbitrary sequence
of characters that makes up the string content, a dollar sign, the same tag that began this dollar quote,
and a dollar sign. For example, here are two different ways to specify the string “Dianne’s horse”
using dollar quoting:

$$Dianne’s horse$$
$$SomeTag$$Dianne’s horse$$SomeTag$$

Notice that inside the dollar-quoted string, single quotes can be used without needing to be escaped.
Indeed, no characters inside a dollar-quoted string are ever escaped: the string content is always writ-
ten literally. Backslashes are not special, and neither are dollar signs, unless they are part of a sequence
matching the opening tag.

It is possible to nest dollar-quoted string constants by choosing different tags at each nesting level.
This is most commonly used in writing function definitions. For example:

$function$
BEGIN
   RETURN ($1 ~ $q$
   \$
   \$
   )
END;
$function$

Here, the sequence $q$

\$
\$
represents a dollar-quoted literal string \$
\$
, which will be recognized when the function body is executed by PostgreSQL. But since the sequence
does not match the outer dollar quoting delimiter $function$, it is just some more characters within
the constant so far as the outer string is concerned.

The tag, if any, of a dollar-quoted string follows the same rules as an unquoted identifier, except that
it cannot contain a dollar sign. Tags are case sensitive, so $tag$String content$tag$ is correct,
but $TAG$String content$tag$ is not.

A dollar-quoted string that follows a keyword or identifier must be separated from it by whitespace;
otherwise the dollar quoting delimiter would be taken as part of the preceding identifier.

Dollar quoting is not part of the SQL standard, but it is often a more convenient way to write com-
licated string literals than the standard-compliant single quote syntax. It is particularly useful when
representing string constants inside other constants, as is often needed in procedural function defini-
tions. With single-quote syntax, each backslash in the above example would have to be written as four
backslashes, which would be reduced to two backslashes in parsing the original string constant, and
then to one when the inner string constant is re-parsed during function execution.

### 4.1.2.3. Bit-String Constants

Bit-string constants look like regular string constants with a B (upper or lower case) immediately
before the opening quote (no intervening whitespace), e.g., B’1001’. The only characters allowed
within bit-string constants are 0 and 1.

Alternatively, bit-string constants can be specified in hexadecimal notation, using a leading X (upper
or lower case), e.g., X’1FF’. This notation is equivalent to a bit-string constant with four binary digits
for each hexadecimal digit.

Both forms of bit-string constant can be continued across lines in the same way as regular string
constants. Dollar quoting cannot be used in a bit-string constant.
4.1.2.4. Numeric Constants

Numeric constants are accepted in these general forms:

\[ \text{digits} \]
\[ \text{digits.}[\text{digits}][e[+-]\text{digits}] \]
\[ [\text{digits}].\text{digits}[e[+-]\text{digits}] \]
\[ \text{digitse[+-]}\text{digits} \]

where \( \text{digits} \) is one or more decimal digits (0 through 9). At least one digit must be before or after the decimal point, if one is used. At least one digit must follow the exponent marker (\( e \)), if one is present. There cannot be any spaces or other characters embedded in the constant. Note that any leading plus or minus sign is not actually considered part of the constant; it is an operator applied to the constant.

These are some examples of valid numeric constants:

42
3.5
4.
.001
5e2
1.925e-3

A numeric constant that contains neither a decimal point nor an exponent is initially presumed to be type \text{integer} if its value fits in type \text{integer} (32 bits); otherwise it is presumed to be type \text{bigint} if its value fits in type \text{bigint} (64 bits); otherwise it is taken to be type \text{numeric}. Constants that contain decimal points and/or exponents are always initially presumed to be type \text{numeric}.

The initially assigned data type of a numeric constant is just a starting point for the type resolution algorithms. In most cases the constant will be automatically coerced to the most appropriate type depending on context. When necessary, you can force a numeric value to be interpreted as a specific data type by casting it. For example, you can force a numeric value to be treated as type \text{real} (\text{float}4) by writing:

\text{REAL} ‘1.23’ -- string style
1.23::REAL -- PostgreSQL (historical) style

These are actually just special cases of the general casting notations discussed next.

4.1.2.5. Constants of Other Types

A constant of an \textit{arbitrary} type can be entered using any one of the following notations:

\text{type} ‘\text{string}'
\text{‘string’::type}
\text{CAST} (‘\text{string}' AS \text{type})

The string constant’s text is passed to the input conversion routine for the type called \text{type}. The result is a constant of the indicated type. The explicit type cast can be omitted if there is no ambiguity as to the type the constant must be (for example, when it is assigned directly to a table column), in which case it is automatically coerced.

The string constant can be written using either regular SQL notation or dollar-quoting.
It is also possible to specify a type coercion using a function-like syntax:

```sql
typename ( 'string' )
```

but not all type names can be used in this way; see Section 4.2.8 for details.

The `::`, `CAST()`, and function-call syntaxes can also be used to specify run-time type conversions of arbitrary expressions, as discussed in Section 4.2.8. To avoid syntactic ambiguity, the `type 'string'` syntax can only be used to specify the type of a simple literal constant. Another restriction on the `type 'string'` syntax is that it does not work for array types; use `::` or `CAST()` to specify the type of an array constant.

The `CAST()` syntax conforms to SQL. The `type 'string'` syntax is a generalization of the standard: SQL specifies this syntax only for a few data types, but PostgreSQL allows it for all types. The syntax with `::` is historical PostgreSQL usage, as is the function-call syntax.

### 4.1.3. Operators

An operator name is a sequence of up to `NAMEDATALEN`-1 (63 by default) characters from the following list:

```sql
+-*/<>=~-!@#$%^&|?'\n```

There are a few restrictions on operator names, however:

- `- -` and `/ *` cannot appear anywhere in an operator name, since they will be taken as the start of a comment.
- A multiple-character operator name cannot end in `+` or `-`, unless the name also contains at least one of these characters:
  ```sql
  ~ ! @ # % ^ & | ?
  ```
  For example, `@ -` is an allowed operator name, but `* -` is not. This restriction allows PostgreSQL to parse SQL-compliant queries without requiring spaces between tokens.

When working with non-SQL-standard operator names, you will usually need to separate adjacent operators with spaces to avoid ambiguity. For example, if you have defined a left unary operator named `@`, you cannot write `X @ Y`; you must write `X @ Y` to ensure that PostgreSQL reads it as two operator names not one.

### 4.1.4. Special Characters

Some characters that are not alphanumeric have a special meaning that is different from being an operator. Details on the usage can be found at the location where the respective syntax element is described. This section only exists to advise the existence and summarize the purposes of these characters.

- A dollar sign (`$`) followed by digits is used to represent a positional parameter in the body of a function definition or a prepared statement. In other contexts the dollar sign can be part of an
identifier or a dollar-quoted string constant.

- Parentheses (()) have their usual meaning to group expressions and enforce precedence. In some cases parentheses are required as part of the fixed syntax of a particular SQL command.
- Brackets ([])) are used to select the elements of an array. See Section 8.14 for more information on arrays.
- Commas (,) are used in some syntactical constructs to separate the elements of a list.
- The semicolon (;) terminates an SQL command. It cannot appear anywhere within a command, except within a string constant or quoted identifier.
- The colon (:) is used to select “slices” from arrays. (See Section 8.14.) In certain SQL dialects (such as Embedded SQL), the colon is used to prefix variable names.
- The asterisk (*) is used in some contexts to denote all the fields of a table row or composite value. It also has a special meaning when used as the argument of an aggregate function, namely that the aggregate does not require any explicit parameter.
- The period (.) is used in numeric constants, and to separate schema, table, and column names.

4.1.5. Comments

A comment is an arbitrary sequence of characters beginning with double dashes and extending to the end of the line, e.g.:

```sql
-- This is a standard SQL comment
```

Alternatively, C-style block comments can be used:

```sql
/* multiline comment
 * with nesting: /* nested block comment */
 */
```

where the comment begins with /* and extends to the matching occurrence of */. These block comments nest, as specified in the SQL standard but unlike C, so that one can comment out larger blocks of code that might contain existing block comments.

A comment is removed from the input stream before further syntax analysis and is effectively replaced by whitespace.

4.1.6. Lexical Precedence

Table 4-1 shows the precedence and associativity of the operators in PostgreSQL. Most operators have the same precedence and are left-associative. The precedence and associativity of the operators is hard-wired into the parser. This can lead to non-intuitive behavior; for example the Boolean operators < and > have a different precedence than the Boolean operators <= and >=. Also, you will sometimes need to add parentheses when using combinations of binary and unary operators. For instance:

```sql
SELECT 5 ! - 6;
```

will be parsed as:
SELECT 5 ! (- 6);

because the parser has no idea — until it is too late — that ! is defined as a postfix operator, not an infix one. To get the desired behavior in this case, you must write:

SELECT (5 !) - 6;

This is the price one pays for extensibility.

Table 4-1. Operator Precedence (decreasing)

<table>
<thead>
<tr>

<td>left</td>
<td>logical disjunction</td>
</tr>
</tbody>
</table>

Note that the operator precedence rules also apply to user-defined operators that have the same names as the built-in operators mentioned above. For example, if you define a “+” operator for some custom data type it will have the same precedence as the built-in “+” operator, no matter what yours does.

When a schema-qualified operator name is used in the `OPERATOR` syntax, as for example in:

SELECT 3 OPERATOR(pg_catalog.+ 4);

the `OPERATOR` construct is taken to have the default precedence shown in Table 4-1 for “any other” operator. This is true no matter which specific operator name appears inside `OPERATOR()`.
4.2. Value Expressions

Value expressions are used in a variety of contexts, such as in the target list of the `SELECT` command, as new column values in `INSERT` or `UPDATE`, or in search conditions in a number of commands. The result of a value expression is sometimes called a *scalar*, to distinguish it from the result of a table expression (which is a table). Value expressions are therefore also called *scalar expressions* (or even simply *expressions*). The expression syntax allows the calculation of values from primitive parts using arithmetic, logical, set, and other operations.

A value expression is one of the following:

- A constant or literal value.
- A column reference.
- A positional parameter reference, in the body of a function definition or prepared statement.
- A subscripted expression.
- A field selection expression.
- An operator invocation.
- A function call.
- An aggregate expression.
- A type cast.
- A scalar subquery.
- An array constructor.
- A row constructor.
- Another value expression in parentheses, useful to group subexpressions and override precedence.

In addition to this list, there are a number of constructs that can be classified as an expression but do not follow any general syntax rules. These generally have the semantics of a function or operator and are explained in the appropriate location in Chapter 9. An example is the `IS NULL` clause.

We have already discussed constants in Section 4.1.2. The following sections discuss the remaining options.

4.2.1. Column References

A column can be referenced in the form

```
correlation.columnname
```

`correlation` is the name of a table (possibly qualified with a schema name), or an alias for a table defined by means of a `FROM` clause, or one of the key words `NEW` or `OLD`, (`NEW` and `OLD` can only appear in rewrite rules, while other correlation names can be used in any SQL statement.) The correlation name and separating dot can be omitted if the column name is unique across all the tables being used in the current query. (See also Chapter 7.)
4.2.2. Positional Parameters

A positional parameter reference is used to indicate a value that is supplied externally to an SQL statement. Parameters are used in SQL function definitions and in prepared queries. Some client libraries also support specifying data values separately from the SQL command string, in which case parameters are used to refer to the out-of-line data values. The form of a parameter reference is:

$number$

For example, consider the definition of a function, `dept`, as:

```sql
CREATE FUNCTION dept(text) RETURNS dept
    AS $$ SELECT * FROM dept WHERE name = $1 $$
    LANGUAGE SQL;
```

Here the `$1` references the value of the first function argument whenever the function is invoked.

4.2.3. Subscripts

If an expression yields a value of an array type, then a specific element of the array value can be extracted by writing:

`expression[subscript]`

or multiple adjacent elements (an “array slice”) can be extracted by writing:

`expression[lower_subscript:upper_subscript]`

(Here, the brackets `[ ]` are meant to appear literally.) Each `subscript` is itself an expression, which must yield an integer value.

In general the array `expression` must be parenthesized, but the parentheses can be omitted when the expression to be subscripted is just a column reference or positional parameter. Also, multiple subscripts can be concatenated when the original array is multidimensional. For example:

```sql
mytable.arraycolumn[4]
mytable.two_d_column[17][34]
$1[10:42]
(arrayfunction(a,b))[42]
```

The parentheses in the last example are required. See Section 8.14 for more about arrays.

4.2.4. Field Selection

If an expression yields a value of a composite type (row type), then a specific field of the row can be extracted by writing:

`expression.fieldname`

In general the row `expression` must be parenthesized, but the parentheses can be omitted when the expression to be selected from is just a table reference or positional parameter. For example:
mytable.mycolumn
$1.somecolumn
(rowfunction(a,b)).col3

(Thus, a qualified column reference is actually just a special case of the field selection syntax.)

### 4.2.5. Operator Invocations

There are three possible syntaxes for an operator invocation:

- `expression operator expression` (binary infix operator)
- `operator expression` (unary prefix operator)
- `expression operator` (unary postfix operator)

where the *operator* token follows the syntax rules of Section 4.1.3, or is one of the key words **AND**, **OR**, and **NOT**, or is a qualified operator name in the form

```
OPERATOR(schema.operatorname)
```

Which particular operators exist and whether they are unary or binary depends on what operators have been defined by the system or the user. Chapter 9 describes the built-in operators.

### 4.2.6. Function Calls

The syntax for a function call is the name of a function (possibly qualified with a schema name), followed by its argument list enclosed in parentheses:

```
function ([expression [ , expression ... ]] )
```

For example, the following computes the square root of 2:

```
sqrt(2)
```

The list of built-in functions is in Chapter 9. Other functions can be added by the user.

### 4.2.7. Aggregate Expressions

An *aggregate expression* represents the application of an aggregate function across the rows selected by a query. An aggregate function reduces multiple inputs to a single output value, such as the sum or average of the inputs. The syntax of an aggregate expression is one of the following:

- `aggregate_name (expression [ , ... ] )`
- `aggregate_name (ALL expression [ , ... ] )`
- `aggregate_name (DISTINCT expression [ , ... ] )`
- `aggregate_name ( * )`

where `aggregate_name` is a previously defined aggregate (possibly qualified with a schema name), and `expression` is any value expression that does not itself contain an aggregate expression.
The first form of aggregate expression invokes the aggregate across all input rows for which the given expression(s) yield non-null values. (Actually, it is up to the aggregate function whether to ignore null values or not — but all the standard ones do.) The second form is the same as the first, since \texttt{ALL} is the default. The third form invokes the aggregate for all distinct non-null values of the expressions found in the input rows. The last form invokes the aggregate once for each input row regardless of null or non-null values; since no particular input value is specified, it is generally only useful for the \texttt{count(*)} aggregate function.

For example, \texttt{count(*)} yields the total number of input rows; \texttt{count(f1)} yields the number of input rows in which \texttt{f1} is non-null; \texttt{count(distinct f1)} yields the number of distinct non-null values of \texttt{f1}.

The predefined aggregate functions are described in Section 9.18. Other aggregate functions can be added by the user.

An aggregate expression can only appear in the result list or \texttt{HAVING} clause of a \texttt{SELECT} command. It is forbidden in other clauses, such as \texttt{WHERE}, because those clauses are logically evaluated before the results of aggregates are formed.

When an aggregate expression appears in a subquery (see Section 4.2.9 and Section 9.19), the aggregate is normally evaluated over the rows of the subquery. But an exception occurs if the aggregate’s arguments contain only outer-level variables: the aggregate then belongs to the nearest such outer level, and is evaluated over the rows of that query. The aggregate expression as a whole is then an outer reference for the subquery it appears in, and acts as a constant over any one evaluation of that subquery. The restriction about appearing only in the result list or \texttt{HAVING} clause applies with respect to the query level that the aggregate belongs to.

\textbf{Note:} PostgreSQL currently \textbf{does not} support \texttt{DISTINCT} with more than one input expression.

### 4.2.8. Type Casts

A type cast specifies a conversion from one data type to another. PostgreSQL accepts two equivalent syntaxes for type casts:

\begin{verbatim}
CAST ( expression AS type )
expression::type
\end{verbatim}

The \texttt{CAST} syntax conforms to SQL; the syntax with \texttt{::} is historical PostgreSQL usage.

When a cast is applied to a value expression of a known type, it represents a run-time type conversion. The cast will succeed only if a suitable type conversion operation has been defined. Notice that this is subtly different from the use of casts with constants, as shown in Section 4.1.2.5. A cast applied to an unadorned string literal represents the initial assignment of a type to a literal constant value, and so it will succeed for any type (if the contents of the string literal are acceptable input syntax for the data type).

An explicit type cast can usually be omitted if there is no ambiguity as to the type that a value expression must produce (for example, when it is assigned to a table column); the system will automatically apply a type cast in such cases. However, automatic casting is only done for casts that are marked “OK to apply implicitly” in the system catalogs. Other casts must be invoked with explicit casting syntax. This restriction is intended to prevent surprising conversions from being applied silently.

It is also possible to specify a type cast using a function-like syntax:
However, this only works for types whose names are also valid as function names. For example, \texttt{double precision} cannot be used this way, but the equivalent \texttt{float8} can. Also, the names \texttt{interval}, \texttt{time}, and \texttt{timestamp} can only be used in this fashion if they are double-quoted, because of syntactic conflicts. Therefore, the use of the function-like cast syntax leads to inconsistencies and should probably be avoided in new applications.

\textbf{Note:} The function-like syntax is in fact just a function call. When one of the two standard cast syntaxes is used to do a run-time conversion, it will internally invoke a registered function to perform the conversion. By convention, these conversion functions have the same name as their output type, and thus the “function-like syntax” is nothing more than a direct invocation of the underlying conversion function. Obviously, this is not something that a portable application should rely on. For further details see \texttt{CREATE CAST}.

4.2.9. Scalar Subqueries

A scalar subquery is an ordinary \texttt{SELECT} query in parentheses that returns exactly one row with one column. (See Chapter 7 for information about writing queries.) The \texttt{SELECT} query is executed and the single returned value is used in the surrounding value expression. It is an error to use a query that returns more than one row or more than one column as a scalar subquery. (But if, during a particular execution, the subquery returns no rows, there is no error; the scalar result is taken to be null.) The subquery can refer to variables from the surrounding query, which will act as constants during any one evaluation of the subquery. See also Section 9.19 for other expressions involving subqueries.

For example, the following finds the largest city population in each state:

\begin{verbatim}
SELECT name, (SELECT max(pop) FROM cities WHERE cities.state = states.name)
FROM states;
\end{verbatim}

4.2.10. Array Constructors

An array constructor is an expression that builds an array value from values for its member elements. A simple array constructor consists of the key word \texttt{ARRAY}, a left square bracket \texttt{[}, one or more expressions (separated by commas) for the array element values, and finally a right square bracket \texttt{]}. For example:

\begin{verbatim}
SELECT ARRAY[1,2,3+4];
array
----------
{1,2,7}
(1 row)
\end{verbatim}

The array element type is the common type of the member expressions, determined using the same rules as for \texttt{UNION} or \texttt{CASE} constructs (see Section 10.5).

Multidimensional array values can be built by nesting array constructors. In the inner constructors, the key word \texttt{ARRAY} can be omitted. For example, these produce the same result:

\begin{verbatim}
SELECT ARRAY[ARRAY[1,2], ARRAY[3,4]];
\end{verbatim}
array
-------------------
{{1,2},{3,4}}
(1 row)

SELECT ARRAY[[1,2],[3,4]];
array
-------------------
{{1,2},{3,4}}
(1 row)

Since multidimensional arrays must be rectangular, inner constructors at the same level must produce sub-arrays of identical dimensions.

Multidimensional array constructor elements can be anything yielding an array of the proper kind, not only a sub-ARRAY construct. For example:

CREATE TABLE arr(f1 int[], f2 int[]);

INSERT INTO arr VALUES (ARRAY[[1,2],[3,4]], ARRAY[[5,6],[7,8]]);

SELECT ARRAY[f1, f2, '{{9,10},{11,12}}'::int[]] FROM arr;
array
----------------------------------------------
{{1,2},{3,4}},{{5,6},{7,8}},{{9,10},{11,12}}
(1 row)

It is also possible to construct an array from the results of a subquery. In this form, the array constructor is written with the key word ARRAY followed by a parenthesized (not bracketed) subquery. For example:

SELECT ARRAY(SELECT oid FROM pg_proc WHERE proname LIKE 'bytea%');
?column?
-------------------------------------------------------------
(1 row)

The subquery must return a single column. The resulting one-dimensional array will have an element for each row in the subquery result, with an element type matching that of the subquery’s output column.

The subscripts of an array value built with ARRAY always begin with one. For more information about arrays, see Section 8.14.

### 4.2.11. Row Constructors

A row constructor is an expression that builds a row value (also called a composite value) from values for its member fields. A row constructor consists of the key word ROW, a left parenthesis, zero or more expressions (separated by commas) for the row field values, and finally a right parenthesis. For example:

SELECT ROW(1,2.5,'this is a test');

The key word ROW is optional when there is more than one expression in the list.
A row constructor can include the syntax `rowvalue.*`, which will be expanded to a list of the elements of the row value, just as occurs when the `.*` syntax is used at the top level of a `SELECT` list. For example, if table `t` has columns `f1` and `f2`, these are the same:

```
SELECT ROW(t.*, 42) FROM t;
SELECT ROW(t.f1, t.f2, 42) FROM t;
```

**Note:** Before PostgreSQL 8.2, the `.*` syntax was not expanded, so that writing `ROW(t.*, 42)` created a two-field row whose first field was another row value. The new behavior is usually more useful. If you need the old behavior of nested row values, write the inner row value without `.*`, for instance `ROW(t, 42).

By default, the value created by a `ROW` expression is of an anonymous record type. If necessary, it can be cast to a named composite type — either the row type of a table, or a composite type created with `CREATE TYPE AS`. An explicit cast might be needed to avoid ambiguity. For example:

```
CREATE TABLE mytable(f1 int, f2 float, f3 text);
CREATE FUNCTION getf1(mytable) RETURNS int AS 'SELECT $1.f1' LANGUAGE SQL;
-- No cast needed since only one getf1() exists
SELECT getf1(ROW(1,2.5,'this is a test'));
getf1
-----
1
(1 row)
```

```
CREATE TYPE myrowtype AS (f1 int, f2 text, f3 numeric);
CREATE FUNCTION getf1(myrowtype) RETURNS int AS 'SELECT $1.f1' LANGUAGE SQL;
-- Now we need a cast to indicate which function to call:
SELECT getf1(ROW(1,2.5,'this is a test'));
ERROR: function getf1(record) is not unique
SELECT getf1(ROW(1,2.5,'this is a test')::mytable);
getf1
-----
1
(1 row)
```

Row constructors can be used to build composite values to be stored in a composite-type table column, or to be passed to a function that accepts a composite parameter. Also, it is possible to compare two row values or test a row with `IS NULL` or `IS NOT NULL`, for example:

```
SELECT ROW(1,2.5,'this is a test') = ROW(1, 3, 'not the same');
```
Chapter 4. SQL Syntax

SELECT ROW(table.*) IS NULL FROM table; -- detect all-null rows

For more detail see Section 9.20. Row constructors can also be used in connection with subqueries, as discussed in Section 9.19.

4.2.12. Expression Evaluation Rules

The order of evaluation of subexpressions is not defined. In particular, the inputs of an operator or function are not necessarily evaluated left-to-right or in any other fixed order.

Furthermore, if the result of an expression can be determined by evaluating only some parts of it, then other subexpressions might not be evaluated at all. For instance, if one wrote:

SELECT true OR somefunc();

then somefunc() would (probably) not be called at all. The same would be the case if one wrote:

SELECT somefunc() OR true;

Note that this is not the same as the left-to-right "short-circuiting" of Boolean operators that is found in some programming languages.

As a consequence, it is unwise to use functions with side effects as part of complex expressions. It is particularly dangerous to rely on side effects or evaluation order in WHERE and HAVING clauses, since those clauses are extensively reprocessed as part of developing an execution plan. Boolean expressions (AND/OR/NOT combinations) in those clauses can be reorganized in any manner allowed by the laws of Boolean algebra.

When it is essential to force evaluation order, a CASE construct (see Section 9.16) can be used. For example, this is an untrustworthy way of trying to avoid division by zero in a WHERE clause:

SELECT ... WHERE x > 0 AND y/x > 1.5;

But this is safe:

SELECT ... WHERE CASE WHEN x > 0 THEN y/x > 1.5 ELSE false END;

A CASE construct used in this fashion will defeat optimization attempts, so it should only be done when necessary. (In this particular example, it would be better to sidestep the problem by writing \( y > 1.5 \times x \) instead.)
Chapter 5. Data Definition

This chapter covers how one creates the database structures that will hold one’s data. In a relational database, the raw data is stored in tables, so the majority of this chapter is devoted to explaining how tables are created and modified and what features are available to control what data is stored in the tables. Subsequently, we discuss how tables can be organized into schemas, and how privileges can be assigned to tables. Finally, we will briefly look at other features that affect the data storage, such as inheritance, views, functions, and triggers.

5.1. Table Basics

A table in a relational database is much like a table on paper: It consists of rows and columns. The number and order of the columns is fixed, and each column has a name. The number of rows is variable — it reflects how much data is stored at a given moment. SQL does not make any guarantees about the order of the rows in a table. When a table is read, the rows will appear in random order, unless sorting is explicitly requested. This is covered in Chapter 7. Furthermore, SQL does not assign unique identifiers to rows, so it is possible to have several completely identical rows in a table. This is a consequence of the mathematical model that underlies SQL but is usually not desirable. Later in this chapter we will see how to deal with this issue.

Each column has a data type. The data type constrains the set of possible values that can be assigned to a column and assigns semantics to the data stored in the column so that it can be used for computations. For instance, a column declared to be of a numerical type will not accept arbitrary text strings, and the data stored in such a column can be used for mathematical computations. By contrast, a column declared to be of a character string type will accept almost any kind of data but it does not lend itself to mathematical calculations, although other operations such as string concatenation are available.

PostgreSQL includes a sizable set of built-in data types that fit many applications. Users can also define their own data types. Most built-in data types have obvious names and semantics, so we defer a detailed explanation to Chapter 8. Some of the frequently used data types are integer for whole numbers, numeric for possibly fractional numbers, text for character strings, date for dates, time for time-of-day values, and timestamp for values containing both date and time.

To create a table, you use the aptly named CREATE TABLE command. In this command you specify at least a name for the new table, the names of the columns and the data type of each column. For example:

```
CREATE TABLE my_first_table (
    first_column text,
    second_column integer
);
```

This creates a table named my_first_table with two columns. The first column is named first_column and has a data type of text; the second column has the name second_column and the type integer. The table and column names follow the identifier syntax explained in Section 4.1.1. The type names are usually also identifiers, but there are some exceptions. Note that the column list is comma-separated and surrounded by parentheses.

Of course, the previous example was heavily contrived. Normally, you would give names to your tables and columns that convey what kind of data they store. So let’s look at a more realistic example:

```
CREATE TABLE products {
```
Tip: When you create many interrelated tables it is wise to choose a consistent naming pattern for the tables and columns. For instance, there is a choice of using singular or plural nouns for table names, both of which are favored by some theorist or other.

There is a limit on how many columns a table can contain. Depending on the column types, it is between 250 and 1600. However, defining a table with anywhere near this many columns is highly unusual and often a questionable design.

If you no longer need a table, you can remove it using the `DROP TABLE` command. For example:

```
DROP TABLE my_first_table;
DROP TABLE products;
```

Attempting to drop a table that does not exist is an error. Nevertheless, it is common in SQL script files to unconditionally try to drop each table before creating it, ignoring any error messages, so that the script works whether or not the table exists. (If you like, you can use the `DROP TABLE IF EXISTS` variant to avoid the error messages, but this is not standard SQL.)

If you need to modify a table that already exists look into Section 5.5 later in this chapter.

With the tools discussed so far you can create fully functional tables. The remainder of this chapter is concerned with adding features to the table definition to ensure data integrity, security, or convenience. If you are eager to fill your tables with data now you can skip ahead to Chapter 6 and read the rest of this chapter later.

### 5.2. Default Values

A column can be assigned a default value. When a new row is created and no values are specified for some of the columns, those columns will be filled with their respective default values. A data manipulation command can also request explicitly that a column be set to its default value, without having to know what that value is. (Details about data manipulation commands are in Chapter 6.)

If no default value is declared explicitly, the default value is the null value. This usually makes sense because a null value can be considered to represent unknown data.

In a table definition, default values are listed after the column data type. For example:

```
CREATE TABLE products {
  product_no integer,
  name text,
  price numeric DEFAULT 9.99
};
```

The default value can be an expression, which will be evaluated whenever the default value is inserted (not when the table is created). A common example is that a `timestamp` column can have a default
of \texttt{now()}, so that it gets set to the time of row insertion. Another common example is generating a “serial number” for each row. In PostgreSQL this is typically done by something like:

\begin{verbatim}
CREATE TABLE products {
    product_no integer DEFAULT nextval('products_product_no_seq'),
    ...
};
\end{verbatim}

where the \texttt{nextval()} function supplies successive values from a \textit{sequence object} (see Section 9.15). This arrangement is sufficiently common that there’s a special shorthand for it:

\begin{verbatim}
CREATE TABLE products {
    product_no SERIAL,
    ...
};
\end{verbatim}

The \texttt{SERIAL} shorthand is discussed further in Section 8.1.4.

5.3. Constraints

Data types are a way to limit the kind of data that can be stored in a table. For many applications, however, the constraint they provide is too coarse. For example, a column containing a product price should probably only accept positive values. But there is no standard data type that accepts only positive numbers. Another issue is that you might want to constrain column data with respect to other columns or rows. For example, in a table containing product information, there should be only one row for each product number.

To that end, SQL allows you to define constraints on columns and tables. Constraints give you as much control over the data in your tables as you wish. If a user attempts to store data in a column that would violate a constraint, an error is raised. This applies even if the value came from the default value definition.

5.3.1. Check Constraints

A check constraint is the most generic constraint type. It allows you to specify that the value in a certain column must satisfy a Boolean (truth-value) expression. For instance, to require positive product prices, you could use:

\begin{verbatim}
CREATE TABLE products {
    product_no integer,
    name text,
    price numeric CHECK (price > 0)
};
\end{verbatim}

As you see, the constraint definition comes after the data type, just like default value definitions. Default values and constraints can be listed in any order. A check constraint consists of the key word \texttt{CHECK} followed by an expression in parentheses. The check constraint expression should involve the column thus constrained, otherwise the constraint would not make too much sense.

You can also give the constraint a separate name. This clarifies error messages and allows you to refer to the constraint when you need to change it. The syntax is:
CREATE TABLE products {
    product_no integer,
    name text,
    price numeric CONSTRAINT positive_price CHECK (price > 0)
};

So, to specify a named constraint, use the key word CONSTRAINT followed by an identifier followed by the constraint definition. (If you don’t specify a constraint name in this way, the system chooses a name for you.)

A check constraint can also refer to several columns. Say you store a regular price and a discounted price, and you want to ensure that the discounted price is lower than the regular price:

CREATE TABLE products {
    product_no integer,
    name text,
    price numeric CHECK (price > 0),
    discounted_price numeric CHECK (discounted_price > 0),
    CHECK (price > discounted_price)
};

The first two constraints should look familiar. The third one uses a new syntax. It is not attached to a particular column, instead it appears as a separate item in the comma-separated column list. Column definitions and these constraint definitions can be listed in mixed order.

We say that the first two constraints are column constraints, whereas the third one is a table constraint because it is written separately from any one column definition. Column constraints can also be written as table constraints, while the reverse is not necessarily possible, since a column constraint is supposed to refer to only the column it is attached to. (PostgreSQL doesn’t enforce that rule, but you should follow it if you want your table definitions to work with other database systems.) The above example could also be written as:

CREATE TABLE products {
    product_no integer,
    name text,
    price numeric,
    CHECK (price > 0),
    discounted_price numeric,
    CHECK (discounted_price > 0),
    CHECK (price > discounted_price)
};

or even:

CREATE TABLE products {
    product_no integer,
    name text,
    price numeric CHECK (price > 0),
    discounted_price numeric,
    CHECK (discounted_price > 0 AND price > discounted_price)
};

It’s a matter of taste.

Names can be assigned to table constraints in just the same way as for column constraints:

CREATE TABLE products {
product_no integer,
name text,
price numeric,
CHECK (price > 0),
discounted_price numeric,
CHECK (discounted_price > 0),
CONSTRAINT valid_discount CHECK (price > discounted_price)
);

It should be noted that a check constraint is satisfied if the check expression evaluates to true or the null value. Since most expressions will evaluate to the null value if any operand is null, they will not prevent null values in the constrained columns. To ensure that a column does not contain null values, the not-null constraint described in the next section can be used.

5.3.2. Not-Null Constraints

A not-null constraint simply specifies that a column must not assume the null value. A syntax example:

```
CREATE TABLE products {
  product_no integer NOT NULL,
  name text NOT NULL,
  price numeric
};
```

A not-null constraint is always written as a column constraint. A not-null constraint is functionally equivalent to creating a check constraint `CHECK (column_name IS NOT NULL)`, but in PostgreSQL creating an explicit not-null constraint is more efficient. The drawback is that you cannot give explicit names to not-null constraints created this way.

Of course, a column can have more than one constraint. Just write the constraints one after another:

```
CREATE TABLE products {
  product_no integer NOT NULL,
  name text NOT NULL,
  price numeric NOT NULL CHECK (price > 0)
};
```

The order doesn’t matter. It does not necessarily determine in which order the constraints are checked. The NOT NULL constraint has an inverse: the NULL constraint. This does not mean that the column must be null, which would surely be useless. Instead, this simply selects the default behavior that the column might be null. The NULL constraint is not present in the SQL standard and should not be used in portable applications. (It was only added to PostgreSQL to be compatible with some other database systems.) Some users, however, like it because it makes it easy to toggle the constraint in a script file. For example, you could start with:

```
CREATE TABLE products {
  product_no integer NULL,
  name text NULL,
  price numeric NULL
};
```

and then insert the NOT key word where desired.
5.3.3. Unique Constraints

Unique constraints ensure that the data contained in a column or a group of columns is unique with respect to all the rows in the table. The syntax is:

```sql
CREATE TABLE products {
    product_no integer UNIQUE,
    name text,
    price numeric
};
```

when written as a column constraint, and:

```sql
CREATE TABLE products {
    product_no integer,
    name text,
    price numeric,
    UNIQUE (product_no)
};
```

when written as a table constraint.

If a unique constraint refers to a group of columns, the columns are listed separated by commas:

```sql
CREATE TABLE example {
    a integer,
    b integer,
    c integer,
    UNIQUE (a, c)
};
```

This specifies that the combination of values in the indicated columns is unique across the whole table, though any one of the columns need not be (and ordinarily isn’t) unique.

You can assign your own name for a unique constraint, in the usual way:

```sql
CREATE TABLE products {
    product_no integer CONSTRAINT must_be_different UNIQUE,
    name text,
    price numeric
};
```

In general, a unique constraint is violated when there are two or more rows in the table where the values of all of the columns included in the constraint are equal. However, two null values are not considered equal in this comparison. That means even in the presence of a unique constraint it is possible to store duplicate rows that contain a null value in at least one of the constrained columns. This behavior conforms to the SQL standard, but we have heard that other SQL databases might not follow this rule. So be careful when developing applications that are intended to be portable.
5.3.4. Primary Keys

Technically, a primary key constraint is simply a combination of a unique constraint and a not-null constraint. So, the following two table definitions accept the same data:

```sql
CREATE TABLE products {
    product_no integer UNIQUE NOT NULL,
    name text,
    price numeric
};

CREATE TABLE products {
    product_no integer PRIMARY KEY,
    name text,
    price numeric
};
```

Primary keys can also constrain more than one column; the syntax is similar to unique constraints:

```sql
CREATE TABLE example {
    a integer,
    b integer,
    c integer,
    PRIMARY KEY (a, c)
};
```

A primary key indicates that a column or group of columns can be used as a unique identifier for rows in the table. (This is a direct consequence of the definition of a primary key. Note that a unique constraint does not, by itself, provide a unique identifier because it does not exclude null values.) This is useful both for documentation purposes and for client applications. For example, a GUI application that allows modifying row values probably needs to know the primary key of a table to be able to identify rows uniquely.

A table can have at most one primary key. (There can be any number of unique and not-null constraints, which are functionally the same thing, but only one can be identified as the primary key.) Relational database theory dictates that every table must have a primary key. This rule is not enforced by PostgreSQL, but it is usually best to follow it.

5.3.5. Foreign Keys

A foreign key constraint specifies that the values in a column (or a group of columns) must match the values appearing in some row of another table. We say this maintains the referential integrity between two related tables.

Say you have the product table that we have used several times already:

```sql
CREATE TABLE products {
    product_no integer PRIMARY KEY,
    name text,
    price numeric
};
```
Let's also assume you have a table storing orders of those products. We want to ensure that the orders table only contains orders of products that actually exist. So we define a foreign key constraint in the orders table that references the products table:

```sql
CREATE TABLE orders (  
    order_id integer PRIMARY KEY,  
    product_no integer REFERENCES products (product_no),  
    quantity integer  
);  
```

Now it is impossible to create orders with `product_no` entries that do not appear in the products table.

We say that in this situation the orders table is the referencing table and the products table is the referenced table. Similarly, there are referencing and referenced columns.

You can also shorten the above command to:

```sql
CREATE TABLE orders (  
    order_id integer PRIMARY KEY,  
    product_no integer REFERENCES products,  
    quantity integer  
);  
```

because in absence of a column list the primary key of the referenced table is used as the referenced column(s).

A foreign key can also constrain and reference a group of columns. As usual, it then needs to be written in table constraint form. Here is a contrived syntax example:

```sql
CREATE TABLE t1 (  
    a integer PRIMARY KEY,  
    b integer,  
    c integer,  
    FOREIGN KEY (b, c) REFERENCES other_table (c1, c2)  
);  
```

Of course, the number and type of the constrained columns need to match the number and type of the referenced columns.

You can assign your own name for a foreign key constraint, in the usual way.

A table can contain more than one foreign key constraint. This is used to implement many-to-many relationships between tables. Say you have tables about products and orders, but now you want to allow one order to contain possibly many products (which the structure above did not allow). You could use this table structure:

```sql
CREATE TABLE products (  
    product_no integer PRIMARY KEY,  
    name text,  
    price numeric  
);  
CREATE TABLE orders (  
    order_id integer PRIMARY KEY,  
    shipping_address text,  
    ...  
);  
```
CREATE TABLE order_items (  
  product_no integer REFERENCES products,  
  order_id integer REFERENCES orders,  
  quantity integer,  
  PRIMARY KEY (product_no, order_id) 
);  

Notice that the primary key overlaps with the foreign keys in the last table.

We know that the foreign keys disallow creation of orders that do not relate to any products. But what if a product is removed after an order is created that references it? SQL allows you to handle that as well. Intuitively, we have a few options:

- Disallow deleting a referenced product
- Delete the orders as well
- Something else?

To illustrate this, let’s implement the following policy on the many-to-many relationship example above: when someone wants to remove a product that is still referenced by an order (via order_items), we disallow it. If someone removes an order, the order items are removed as well:

```
CREATE TABLE products (
  product_no integer PRIMARY KEY,
  name text,
  price numeric
);  
 CREATE TABLE orders (  
  order_id integer PRIMARY KEY,
  shipping_address text,
  ...  
);  
 CREATE TABLE order_items (  
  product_no integer REFERENCES products ON DELETE RESTRICT,
  order_id integer REFERENCES orders ON DELETE CASCADE,
  quantity integer,
  PRIMARY KEY (product_no, order_id)
);  
```

Restricting and cascading deletes are the two most common options. RESTRICT prevents deletion of a referenced row. NO ACTION means that if any referencing rows still exist when the constraint is checked, an error is raised; this is the default behavior if you do not specify anything. (The essential difference between these two choices is that NO ACTION allows the check to be deferred until later in the transaction, whereas RESTRICT does not.) CASCADE specifies that when a referenced row is deleted, row(s) referencing it should be automatically deleted as well. There are two other options: SET NULL and SET DEFAULT. These cause the referencing columns to be set to nulls or default values, respectively, when the referenced row is deleted. Note that these do not excuse you from observing any constraints. For example, if an action specifies SET DEFAULT but the default value would not satisfy the foreign key, the operation will fail.

Analogous to ON DELETE there is also ON UPDATE which is invoked when a referenced column is changed (updated). The possible actions are the same.
More information about updating and deleting data is in Chapter 6.

Finally, we should mention that a foreign key must reference columns that either are a primary key or form a unique constraint. If the foreign key references a unique constraint, there are some additional possibilities regarding how null values are matched. These are explained in the reference documentation for \textit{CREATE TABLE}.

### 5.4. System Columns

Every table has several \textit{system columns} that are implicitly defined by the system. Therefore, these names cannot be used as names of user-defined columns. (Note that these restrictions are separate from whether the name is a key word or not; quoting a name will not allow you to escape these restrictions.) You do not really need to be concerned about these columns, just know they exist.

\textbf{oid}

The object identifier (object ID) of a row. This column is only present if the table was created using \texttt{WITH OIDS}, or if the default\textunderscore with\textunderscore oids configuration variable was set at the time. This column is of type \texttt{oid} (same name as the column); see Section 8.16 for more information about the type.

\textbf{tableoid}

The OID of the table containing this row. This column is particularly handy for queries that select from inheritance hierarchies (see Section 5.8), since without it, it’s difficult to tell which individual table a row came from. The \texttt{tableoid} can be joined against the \texttt{oid} column of \texttt{pg\_class} to obtain the table name.

\textbf{xmin}

The identity (transaction ID) of the inserting transaction for this row version. (A row version is an individual state of a row; each update of a row creates a new row version for the same logical row.)

\textbf{cmin}

The command identifier (starting at zero) within the inserting transaction.

\textbf{xmax}

The identity (transaction ID) of the deleting transaction, or zero for an undeleted row version. It is possible for this column to be nonzero in a visible row version. That usually indicates that the deleting transaction hasn’t committed yet, or that an attempted deletion was rolled back.

\textbf{cmax}

The command identifier within the deleting transaction, or zero.

\textbf{ctid}

The physical location of the row version within its table. Note that although the \texttt{ctid} can be used to locate the row version very quickly, a row’s \texttt{ctid} will change if it is updated or moved by \texttt{VACUUM FULL}. Therefore \texttt{ctid} is useless as a long-term row identifier. The OID, or even better a user-defined serial number, should be used to identify logical rows.

OIDs are 32-bit quantities and are assigned from a single cluster-wide counter. In a large or long-lived database, it is possible for the counter to wrap around. Hence, it is bad practice to assume that OIDs are unique, unless you take steps to ensure that this is the case. If you need to identify the rows in
a table, using a sequence generator is strongly recommended. However, OIDs can be used as well, provided that a few additional precautions are taken:

- A unique constraint should be created on the OID column of each table for which the OID will be used to identify rows. When such a unique constraint (or unique index) exists, the system takes care not to generate an OID matching an already-existing row. (Of course, this is only possible if the table contains fewer than $2^{32}$ (4 billion) rows, and in practice the table size had better be much less than that, or performance might suffer.)

- OIDs should never be assumed to be unique across tables; use the combination of tableoid and row OID if you need a database-wide identifier.

- Of course, the tables in question must be created WITH OIDS. As of PostgreSQL 8.1, WITHOUT OIDS is the default.

Transaction identifiers are also 32-bit quantities. In a long-lived database it is possible for transaction IDs to wrap around. This is not a fatal problem given appropriate maintenance procedures; see Chapter 23 for details. It is unwise, however, to depend on the uniqueness of transaction IDs over the long term (more than one billion transactions).

Command identifiers are also 32-bit quantities. This creates a hard limit of $2^{32}$ (4 billion) SQL commands within a single transaction. In practice this limit is not a problem — note that the limit is on number of SQL commands, not number of rows processed. Also, as of PostgreSQL 8.3, only commands that actually modify the database contents will consume a command identifier.

### 5.5. Modifying Tables

When you create a table and you realize that you made a mistake, or the requirements of the application change, then you can drop the table and create it again. But this is not a convenient option if the table is already filled with data, or if the table is referenced by other database objects (for instance a foreign key constraint). Therefore PostgreSQL provides a family of commands to make modifications to existing tables. Note that this is conceptually distinct from altering the data contained in the table: here we are interested in altering the definition, or structure, of the table.

You can

- Add columns,
- Remove columns,
- Add constraints,
- Remove constraints,
- Change default values,
- Change column data types,
- Rename columns,
- Rename tables.

All these actions are performed using the `ALTER TABLE` command, whose reference page contains details beyond those given here.
5.5.1. Adding a Column

To add a column, use a command like this:

```
ALTER TABLE products ADD COLUMN description text;
```

The new column is initially filled with whatever default value is given (null if you don’t specify a `DEFAULT` clause).

You can also define constraints on the column at the same time, using the usual syntax:

```
ALTER TABLE products ADD COLUMN description text CHECK (description <> '');
```

In fact all the options that can be applied to a column description in `CREATE TABLE` can be used here. Keep in mind however that the default value must satisfy the given constraints, or the `ADD` will fail. Alternatively, you can add constraints later (see below) after you’ve filled in the new column correctly.

**Tip:** Adding a column with a default requires updating each row of the table (to store the new column value). However, if no default is specified, PostgreSQL is able to avoid the physical update. So if you intend to fill the column with mostly nondefault values, it’s best to add the column with no default, insert the correct values using `UPDATE`, and then add any desired default as described below.

5.5.2. Removing a Column

To remove a column, use a command like this:

```
ALTER TABLE products DROP COLUMN description;
```

Whatever data was in the column disappears. Table constraints involving the column are dropped, too. However, if the column is referenced by a foreign key constraint of another table, PostgreSQL will not silently drop that constraint. You can authorize dropping everything that depends on the column by adding `CASCADE`:

```
ALTER TABLE products DROP COLUMN description CASCADE;
```

See Section 5.11 for a description of the general mechanism behind this.

5.5.3. Adding a Constraint

To add a constraint, the table constraint syntax is used. For example:

```
ALTER TABLE products ADD CHECK (name <> '');
ALTER TABLE products ADD CONSTRAINT some_name UNIQUE (product_no);
ALTER TABLE products ADD FOREIGN KEY (product_group_id) REFERENCES product_groups;
```

To add a not-null constraint, which cannot be written as a table constraint, use this syntax:

```
ALTER TABLE products ALTER COLUMN product_no SET NOT NULL;
```
Chapter 5. Data Definition

The constraint will be checked immediately, so the table data must satisfy the constraint before it can be added.

5.5.4. Removing a Constraint

To remove a constraint you need to know its name. If you gave it a name then that’s easy. Otherwise the system assigned a generated name, which you need to find out. The psql command `\d tablename` can be helpful here; other interfaces might also provide a way to inspect table details. Then the command is:

```
ALTER TABLE products DROP CONSTRAINT some_name;
```

(If you are dealing with a generated constraint name like `$2`, don’t forget that you’ll need to double-quote it to make it a valid identifier.)

As with dropping a column, you need to add `CASCADE` if you want to drop a constraint that something else depends on. An example is that a foreign key constraint depends on a unique or primary key constraint on the referenced column(s).

This works the same for all constraint types except not-null constraints. To drop a not null constraint use:

```
ALTER TABLE products ALTER COLUMN product_no DROP NOT NULL;
```

(Recall that not-null constraints do not have names.)

5.5.5. Changing a Column’s Default Value

To set a new default for a column, use a command like this:

```
ALTER TABLE products ALTER COLUMN price SET DEFAULT 7.77;
```

Note that this doesn’t affect any existing rows in the table, it just changes the default for future `INSERT` commands.

To remove any default value, use:

```
ALTER TABLE products ALTER COLUMN price DROP DEFAULT;
```

This is effectively the same as setting the default to null. As a consequence, it is not an error to drop a default where one hadn’t been defined, because the default is implicitly the null value.

5.5.6. Changing a Column’s Data Type

To convert a column to a different data type, use a command like this:

```
ALTER TABLE products ALTER COLUMN price TYPE numeric(10,2);
```

This will succeed only if each existing entry in the column can be converted to the new type by an implicit cast. If a more complex conversion is needed, you can add a `USING` clause that specifies how to compute the new values from the old.

PostgreSQL will attempt to convert the column’s default value (if any) to the new type, as well as any constraints that involve the column. But these conversions might fail, or might produce surprising
results. It’s often best to drop any constraints on the column before altering its type, and then add back suitably modified constraints afterwards.

5.5.7. Renaming a Column

To rename a column:

```
ALTER TABLE products RENAME COLUMN product_no TO product_number;
```

5.5.8. Renaming a Table

To rename a table:

```
ALTER TABLE products RENAME TO items;
```

5.6. Privileges

When you create a database object, you become its owner. By default, only the owner of an object can do anything with the object. In order to allow other users to use it, privileges must be granted. (However, users that have the superuser attribute can always access any object.)

There are several different privileges: SELECT, INSERT, UPDATE, DELETE, REFERENCES, TRIGGER, CREATE, CONNECT, TEMPORARY, EXECUTE, and USAGE. The privileges applicable to a particular object vary depending on the object’s type (table, function, etc). For complete information on the different types of privileges supported by PostgreSQL, refer to the `GRANT` reference page. The following sections and chapters will also show you how those privileges are used.

The right to modify or destroy an object is always the privilege of the owner only.

**Note:** To change the owner of a table, index, sequence, or view, use the `ALTER TABLE` command. There are corresponding `ALTER` commands for other object types.

To assign privileges, the `GRANT` command is used. For example, if `joe` is an existing user, and `accounts` is an existing table, the privilege to update the table can be granted with:

```
GRANT UPDATE ON accounts TO joe;
```

Writing `ALL` in place of a specific privilege grants all privileges that are relevant for the object type.

The special “user” name `PUBLIC` can be used to grant a privilege to every user on the system. Also, “group” roles can be set up to help manage privileges when there are many users of a database — for details see Chapter 19.

To revoke a privilege, use the fittingly named `REVOKE` command:

```
REVOKE ALL ON accounts FROM PUBLIC;
```
The special privileges of the object owner (i.e., the right to do `DROP`, `GRANT`, `REVOKE`, etc.) are always implicit in being the owner, and cannot be granted or revoked. But the object owner can choose to revoke his own ordinary privileges, for example to make a table read-only for himself as well as others.

Ordinarily, only the object’s owner (or a superuser) can grant or revoke privileges on an object. However, it is possible to grant a privilege “with grant option”, which gives the recipient the right to grant it in turn to others. If the grant option is subsequently revoked then all who received the privilege from that recipient (directly or through a chain of grants) will lose the privilege. For details see the `GRANT` and `REVOKE` reference pages.

5.7. Schemas

A PostgreSQL database cluster contains one or more named databases. Users and groups of users are shared across the entire cluster, but no other data is shared across databases. Any given client connection to the server can access only the data in a single database, the one specified in the connection request.

Note: Users of a cluster do not necessarily have the privilege to access every database in the cluster. Sharing of user names means that there cannot be different users named, say, `joe` in two databases in the same cluster; but the system can be configured to allow `joe` access to only some of the databases.

A database contains one or more named schemas, which in turn contain tables. Schemas also contain other kinds of named objects, including data types, functions, and operators. The same object name can be used in different schemas without conflict; for example, both `schema1` and `myschema` can contain tables named `mytable`. Unlike databases, schemas are not rigidly separated: a user can access objects in any of the schemas in the database he is connected to, if he has privileges to do so.

There are several reasons why one might want to use schemas:

• To allow many users to use one database without interfering with each other.
• To organize database objects into logical groups to make them more manageable.
• Third-party applications can be put into separate schemas so they cannot collide with the names of other objects.

Schemas are analogous to directories at the operating system level, except that schemas cannot be nested.

5.7.1. Creating a Schema

To create a schema, use the `CREATE SCHEMA` command. Give the schema a name of your choice. For example:

```sql
CREATE SCHEMA myschema;
```

To create or access objects in a schema, write a qualified name consisting of the schema name and table name separated by a dot:
This works anywhere a table name is expected, including the table modification commands and the data access commands discussed in the following chapters. (For brevity we will speak of tables only, but the same ideas apply to other kinds of named objects, such as types and functions.)

Actually, the even more general syntax

\[
\text{database.schema.table}
\]

can be used too, but at present this is just for pro forma compliance with the SQL standard. If you write a database name, it must be the same as the database you are connected to.

So to create a table in the new schema, use:

\[
\text{CREATE TABLE myschema.mytable ( ... );}
\]

To drop a schema if it’s empty (all objects in it have been dropped), use:

\[
\text{DROP SCHEMA myschema;}
\]

To drop a schema including all contained objects, use:

\[
\text{DROP SCHEMA myschema CASCADE;}
\]

See Section 5.11 for a description of the general mechanism behind this.

Often you will want to create a schema owned by someone else (since this is one of the ways to restrict the activities of your users to well-defined namespaces). The syntax for that is:

\[
\text{CREATE SCHEMA schemaname AUTHORIZATION username;}
\]

You can even omit the schema name, in which case the schema name will be the same as the user name. See Section 5.7.6 for how this can be useful.

Schema names beginning with `pg_` are reserved for system purposes and cannot be created by users.

### 5.7.2. The Public Schema

In the previous sections we created tables without specifying any schema names. By default, such tables (and other objects) are automatically put into a schema named “public”. Every new database contains such a schema. Thus, the following are equivalent:

\[
\text{CREATE TABLE products { ... };}
\]

and:

\[
\text{CREATE TABLE public.products { ... };}
\]
5.7.3. The Schema Search Path

Qualified names are tedious to write, and it’s often best not to wire a particular schema name into applications anyway. Therefore tables are often referred to by unqualified names, which consist of just the table name. The system determines which table is meant by following a search path, which is a list of schemas to look in. The first matching table in the search path is taken to be the one wanted. If there is no match in the search path, an error is reported, even if matching table names exist in other schemas in the database.

The first schema named in the search path is called the current schema. Aside from being the first schema searched, it is also the schema in which new tables will be created if the `CREATE TABLE` command does not specify a schema name.

To show the current search path, use the following command:

```
SHOW search_path;
```

In the default setup this returns:

```
  search_path
-------------
  "$user",public
```

The first element specifies that a schema with the same name as the current user is to be searched. If no such schema exists, the entry is ignored. The second element refers to the public schema that we have seen already.

The first schema in the search path that exists is the default location for creating new objects. That is the reason that by default objects are created in the public schema. When objects are referenced in any other context without schema qualification (table modification, data modification, or query commands) the search path is traversed until a matching object is found. Therefore, in the default configuration, any unqualified access again can only refer to the public schema.

To put our new schema in the path, we use:

```
SET search_path TO myschema,public;
```

(We omit the `$user` here because we have no immediate need for it.) And then we can access the table without schema qualification:

```
DROP TABLE mytable;
```

Also, since `myschema` is the first element in the path, new objects would by default be created in it.

We could also have written:

```
SET search_path TO myschema;
```

Then we no longer have access to the public schema without explicit qualification. There is nothing special about the public schema except that it exists by default. It can be dropped, too.

See also Section 9.22 for other ways to manipulate the schema search path.

The search path works in the same way for data type names, function names, and operator names as it does for table names. Data type and function names can be qualified in exactly the same way as table names. If you need to write a qualified operator name in an expression, there is a special provision: you must write

```
OPERATOR(schema,operator)
```
This is needed to avoid syntactic ambiguity. An example is:

```
SELECT 3 OPERATOR(pg_catalog.+) 4;
```

In practice one usually relies on the search path for operators, so as not to have to write anything so ugly as that.

### 5.7.4. Schemas and Privileges

By default, users cannot access any objects in schemas they do not own. To allow that, the owner of the schema needs to grant the `USAGE` privilege on the schema. To allow users to make use of the objects in the schema, additional privileges might need to be granted, as appropriate for the object.

A user can also be allowed to create objects in someone else’s schema. To allow that, the `CREATE` privilege on the schema needs to be granted. Note that by default, everyone has `CREATE` and `USAGE` privileges on the schema `public`. This allows all users that are able to connect to a given database to create objects in its `public` schema. If you do not want to allow that, you can revoke that privilege:

```
REVOKE CREATE ON SCHEMA public FROM PUBLIC;
```

(The first “public” is the schema, the second “public” means “every user”. In the first sense it is an identifier, in the second sense it is a key word, hence the different capitalization; recall the guidelines from Section 4.1.1.)

### 5.7.5. The System Catalog Schema

In addition to `public` and user-created schemas, each database contains a `pg_catalog` schema, which contains the system tables and all the built-in data types, functions, and operators. `pg_catalog` is always effectively part of the search path. If it is not named explicitly in the path then it is implicitly searched before searching the path’s schemas. This ensures that built-in names will always be findable. However, you can explicitly place `pg_catalog` at the end of your search path if you prefer to have user-defined names override built-in names.

In PostgreSQL versions before 7.3, table names beginning with `pg_` were reserved. This is no longer true: you can create such a table name if you wish, in any non-system schema. However, it’s best to continue to avoid such names, to ensure that you won’t suffer a conflict if some future version defines a system table named the same as your table. (With the default search path, an unqualified reference to your table name would be resolved as the system table instead.) System tables will continue to follow the convention of having names beginning with `pg_`, so that they will not conflict with unqualified user-table names so long as users avoid the `pg_` prefix.

### 5.7.6. Usage Patterns

Schemas can be used to organize your data in many ways. There are a few usage patterns that are recommended and are easily supported by the default configuration:

- If you do not create any schemas then all users access the public schema implicitly. This simulates the situation where schemas are not available at all. This setup is mainly recommended when there is only a single user or a few cooperating users in a database. This setup also allows smooth transition from the non-schema-aware world.
Chapter 5. Data Definition

• You can create a schema for each user with the same name as that user. Recall that the default
search path starts with $user, which resolves to the user name. Therefore, if each user has a
separate schema, they access their own schemas by default.

If you use this setup then you might also want to revoke access to the public schema (or drop it
altogether), so users are truly constrained to their own schemas.

• To install shared applications (tables to be used by everyone, additional functions provided by third
parties, etc.), put them into separate schemas. Remember to grant appropriate privileges to allow
the other users to access them. Users can then refer to these additional objects by qualifying the
names with a schema name, or they can put the additional schemas into their search path, as they
choose.

5.7.7. Portability

In the SQL standard, the notion of objects in the same schema being owned by different users does
not exist. Moreover, some implementations do not allow you to create schemas that have a different
name than their owner. In fact, the concepts of schema and user are nearly equivalent in a database
system that implements only the basic schema support specified in the standard. Therefore, many
users consider qualified names to really consist of `username.tablename`. This is how PostgreSQL
will effectively behave if you create a per-user schema for every user.

Also, there is no concept of a `public` schema in the SQL standard. For maximum conformance to
the standard, you should not use (perhaps even remove) the `public` schema.

Of course, some SQL database systems might not implement schemas at all, or provide namespace
support by allowing (possibly limited) cross-database access. If you need to work with those systems,
then maximum portability would be achieved by not using schemas at all.

5.8. Inheritance

PostgreSQL implements table inheritance, which can be a useful tool for database designers.
(SQL:1999 and later define a type inheritance feature, which differs in many respects from the
features described here.)

Let’s start with an example: suppose we are trying to build a data model for cities. Each state has many
cities, but only one capital. We want to be able to quickly retrieve the capital city for any particular
state. This can be done by creating two tables, one for state capitals and one for cities that are not
capitals. However, what happens when we want to ask for data about a city, regardless of whether it
is a capital or not? The inheritance feature can help to resolve this problem. We define the `capitals`
table so that it inherits from `cities`:

```
CREATE TABLE cities {
    name text,
    population float,
    altitude int -- in feet
} ;
```

```
CREATE TABLE capitals {
    state char(2)
) INHERITS (cities);
```
In this case, the capitals table *inherits* all the columns of its parent table, cities. State capitals also have an extra column, state, that shows their state.

In PostgreSQL, a table can inherit from zero or more other tables, and a query can reference either all rows of a table or all rows of a table plus all of its descendant tables. The latter behavior is the default. For example, the following query finds the names of all cities, including state capitals, that are located at an altitude over 500 feet:

```sql
SELECT name, altitude
FROM cities
WHERE altitude > 500;
```

Given the sample data from the PostgreSQL tutorial (see Section 2.1), this returns:

<table>
<thead>
<tr>
<th>name</th>
<th>altitude</th>
</tr>
</thead>
<tbody>
<tr>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>Mariposa</td>
<td>1953</td>
</tr>
<tr>
<td>Madison</td>
<td>845</td>
</tr>
</tbody>
</table>

On the other hand, the following query finds all the cities that are not state capitals and are situated at an altitude over 500 feet:

```sql
SELECT name, altitude
FROM ONLY cities
WHERE altitude > 500;
```

Here the `ONLY` keyword indicates that the query should apply only to `cities`, and not any tables below `cities` in the inheritance hierarchy. Many of the commands that we have already discussed — `SELECT`, `UPDATE` and `DELETE` — support the `ONLY` keyword.

You can also write the table name with a trailing `*` to explicitly specify that descendant tables are included:

```sql
SELECT name, altitude
FROM cities*
WHERE altitude > 500;
```

Writing `*` is not necessary, since this behavior is the default (unless you have changed the setting of the `sql_inheritance` configuration option). However writing `*` might be useful to emphasize that additional tables will be searched.

In some cases you might wish to know which table a particular row originated from. There is a system column called `tableoid` in each table which can tell you the originating table:

```sql
SELECT c.tableoid, c.name, c.altitude
FROM cities c
WHERE c.altitude > 500;
```

which returns:
(If you try to reproduce this example, you will probably get different numeric OIDs.) By doing a join with `pg_class` you can see the actual table names:

```
SELECT p.relname, c.name, c.altitude
FROM cities c, pg_class p
WHERE c.altitude > 500 and c.tableoid = p.oid;
```

which returns:

<table>
<thead>
<tr>
<th>relname</th>
<th>name</th>
<th>altitude</th>
</tr>
</thead>
<tbody>
<tr>
<td>cities</td>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>cities</td>
<td>Mariposa</td>
<td>1953</td>
</tr>
<tr>
<td>capitals</td>
<td>Madison</td>
<td>845</td>
</tr>
</tbody>
</table>

Inheritance does not automatically propagate data from `INSERT` or `COPY` commands to other tables in the inheritance hierarchy. In our example, the following `INSERT` statement will fail:

```
INSERT INTO cities (name, population, altitude, state)
VALUES ('New York', NULL, NULL, 'NY');
```

We might hope that the data would somehow be routed to the `capitals` table, but this does not happen: `INSERT` always inserts into exactly the table specified. In some cases it is possible to redirect the insertion using a rule (see Chapter 36). However that does not help for the above case because the `cities` table does not contain the column `state`, and so the command will be rejected before the rule can be applied.

All check constraints and not-null constraints on a parent table are automatically inherited by its children. Other types of constraints (unique, primary key, and foreign key constraints) are not inherited.

A table can inherit from more than one parent table, in which case it has the union of the columns defined by the parent tables. Any columns declared in the child table’s definition are added to these. If the same column name appears in multiple parent tables, or in both a parent table and the child’s definition, then these columns are “merged” so that there is only one such column in the child table. To be merged, columns must have the same data types, else an error is raised. The merged column will have copies of all the check constraints coming from any one of the column definitions it came from, and will be marked not-null if any of them are.

Table inheritance is typically established when the child table is created, using the `INHERITS` clause of the `CREATE TABLE` statement. Alternatively, a table which is already defined in a compatible way can have a new parent relationship added, using the `INHERIT` variant of `ALTER TABLE`. To do this the new child table must already include columns with the same names and types as the columns of the parent. It must also include check constraints with the same names and check expressions as those of the parent. Similarly an inheritance link can be removed from a child using the `NO INHERIT` variant of `ALTER TABLE`. Dynamically adding and removing inheritance links like this can be useful when the inheritance relationship is being used for table partitioning (see Section 5.9).

One convenient way to create a compatible table that will later be made a new child is to use the `LIKE` clause in `CREATE TABLE`. This creates a new table with the same columns as the source table. If there are any check constraints defined on the source table, the `INCLUDING CONSTRAINTS` option to
LIKE should be specified, as the new child must have constraints matching the parent to be considered compatible.

A parent table cannot be dropped while any of its children remain. Neither can columns of child tables be dropped or altered if they are inherited from any parent tables. If you wish to remove a table and all of its descendants, one easy way is to drop the parent table with the \texttt{CASCADE} option. \texttt{ALTER TABLE} will propagate any changes in column data definitions and check constraints down the inheritance hierarchy. Again, dropping columns or constraints on parent tables is only possible when using the \texttt{CASCADE} option. \texttt{ALTER TABLE} follows the same rules for duplicate column merging and rejection that apply during \texttt{CREATE TABLE}.

\section*{5.8.1. Caveats}

Table access permissions are not automatically inherited. Therefore, a user attempting to access a parent table must either have permissions to do the operation on all its child tables as well, or must use the \texttt{ONLY} notation. When adding a new child table to an existing inheritance hierarchy, be careful to grant all the needed permissions on it.

A serious limitation of the inheritance feature is that indexes (including unique constraints) and foreign key constraints only apply to single tables, not to their inheritance children. This is true on both the referencing and referenced sides of a foreign key constraint. Thus, in the terms of the above example:

- If we declared \texttt{cities.name} to be \texttt{UNIQUE} or a \texttt{PRIMARY KEY}, this would not stop the \texttt{capitals} table from having rows with names duplicating rows in \texttt{cities}. And those duplicate rows would by default show up in queries from \texttt{cities}. In fact, by default \texttt{capitals} would have no unique constraint at all, and so could contain multiple rows with the same name. You could add a unique constraint to \texttt{capitals}, but this would not prevent duplication compared to \texttt{cities}.

- Similarly, if we were to specify that \texttt{cities.name REFERENCES} some other table, this constraint would not automatically propagate to \texttt{capitals}. In this case you could work around it by manually adding the same \texttt{REFERENCES} constraint to \texttt{capitals}.

- Specifying that another table’s column \texttt{REFERENCES cities(name)} would allow the other table to contain city names, but not capital names. There is no good workaround for this case.

These deficiencies will probably be fixed in some future release, but in the meantime considerable care is needed in deciding whether inheritance is useful for your problem.

\section*{5.9. Partitioning}

PostgreSQL supports basic table partitioning. This section describes why and how to implement partitioning as part of your database design.

\subsection*{5.9.1. Overview}

Partitioning refers to splitting what is logically one large table into smaller physical pieces. Partitioning can provide several benefits:

- Query performance can be improved dramatically in certain situations, particularly when most of
Chapter 5. Data Definition

the heavily accessed rows of the table are in a single partition or a small number of partitions. The
partitioning substitutes for leading columns of indexes, reducing index size and making it more
likely that the heavily-used parts of the indexes fit in memory.

- When queries or updates access a large percentage of a single partition, performance can be im-
proved by taking advantage of sequential scan of that partition instead of using an index and random
access reads scattered across the whole table.

- Bulk loads and deletes can be accomplished by adding or removing partitions, if that requirement
is planned into the partitioning design. ALTER TABLE is far faster than a bulk operation. It also
totally avoids the VACUUM overhead caused by a bulk DELETE.

- Seldom-used data can be migrated to cheaper and slower storage media.

The benefits will normally be worthwhile only when a table would otherwise be very large. The exact
point at which a table will benefit from partitioning depends on the application, although a rule of
thumb is that the size of the table should exceed the physical memory of the database server.

Currently, PostgreSQL supports partitioning via table inheritance. Each partition must be created as a
child table of a single parent table. The parent table itself is normally empty; it exists just to represent
the entire data set. You should be familiar with inheritance (see Section 5.8) before attempting to set
up partitioning.

The following forms of partitioning can be implemented in PostgreSQL:

Range Partitioning

The table is partitioned into “ranges” defined by a key column or set of columns, with no overlap
between the ranges of values assigned to different partitions. For example one might partition by
date ranges, or by ranges of identifiers for particular business objects.

List Partitioning

The table is partitioned by explicitly listing which key values appear in each partition.

5.9.2. Implementing Partitioning

To set up a partitioned table, do the following:

1. Create the “master” table, from which all of the partitions will inherit.

   This table will contain no data. Do not define any check constraints on this table, unless you
   intend them to be applied equally to all partitions. There is no point in defining any indexes or
   unique constraints on it, either.

2. Create several “child” tables that each inherit from the master table. Normally, these tables will
   not add any columns to the set inherited from the master.

   We will refer to the child tables as partitions, though they are in every way normal PostgreSQL
   tables.

3. Add table constraints to the partition tables to define the allowed key values in each partition.

   Typical examples would be:
   CHECK ( x = 1 )
   CHECK ( county IN ('Oxfordshire', 'Buckinghamshire', 'Warwickshire') )
   CHECK ( outletID >= 100 AND outletID < 200 )
Chapter 5. Data Definition

Ensure that the constraints guarantee that there is no overlap between the key values permitted in different partitions. A common mistake is to set up range constraints like this:

```
CHECK ( outletID BETWEEN 100 AND 200 )
CHECK ( outletID BETWEEN 200 AND 300 )
```

This is wrong since it is not clear which partition the key value 200 belongs in.

Note that there is no difference in syntax between range and list partitioning; those terms are descriptive only.

4. For each partition, create an index on the key column(s), as well as any other indexes you might want. (The key index is not strictly necessary, but in most scenarios it is helpful. If you intend the key values to be unique then you should always create a unique or primary-key constraint for each partition.)

5. Optionally, define a trigger or rule to redirect data inserted into the master table to the appropriate partition.

6. Ensure that the constraint_exclusion configuration parameter is enabled in `postgresql.conf`. Without this, queries will not be optimized as desired.

For example, suppose we are constructing a database for a large ice cream company. The company measures peak temperatures every day as well as ice cream sales in each region. Conceptually, we want a table like this:

```
CREATE TABLE measurement (  
city_id int not null, 
logdate date not null, 
peaktemp int, 
unitsales int 
);
```

We know that most queries will access just the last week’s, month’s or quarter’s data, since the main use of this table will be to prepare online reports for management. To reduce the amount of old data that needs to be stored, we decide to only keep the most recent 3 years worth of data. At the beginning of each month we will remove the oldest month’s data.

In this situation we can use partitioning to help us meet all of our different requirements for the measurements table. Following the steps outlined above, partitioning can be set up as follows:

1. The master table is the `measurement` table, declared exactly as above.

2. Next we create one partition for each active month:

```
CREATE TABLE measurement_y2006m02 ( ) INHERITS (measurement);
CREATE TABLE measurement_y2006m03 ( ) INHERITS (measurement);
...  
CREATE TABLE measurement_y2007m11 ( ) INHERITS (measurement);
CREATE TABLE measurement_y2007m12 ( ) INHERITS (measurement);
CREATE TABLE measurement_y2008m01 ( ) INHERITS (measurement);
```

Each of the partitions are complete tables in their own right, but they inherit their definitions from the `measurement` table.

This solves one of our problems: deleting old data. Each month, all we will need to do is perform a `DROP TABLE` on the oldest child table and create a new child table for the new month’s data.

3. We must provide non-overlapping table constraints. Rather than just creating the partition tables as above, the table creation script should really be:

```
CREATE TABLE measurement_y2006m02 (  
    CHECK ( logdate >= DATE '2006-02-01' AND logdate < DATE '2006-03-01' )  
);
```
Chapter 5. Data Definition

) INHERITS (measurement);  
CREATE TABLE measurement_y2006m03 (  
    CHECK ( logdate >= DATE '2006-03-01' AND logdate < DATE '2006-04-01' )  
) INHERITS (measurement);
...
CREATE TABLE measurement_y2007m11 (  
    CHECK ( logdate >= DATE '2007-11-01' AND logdate < DATE '2007-12-01' )  
) INHERITS (measurement);
CREATE TABLE measurement_y2007m12 (  
    CHECK ( logdate >= DATE '2007-12-01' AND logdate < DATE '2008-01-01' )  
) INHERITS (measurement);
CREATE TABLE measurement_y2008m01 (  
    CHECK ( logdate >= DATE '2008-01-01' AND logdate < DATE '2008-02-01' )  
) INHERITS (measurement);

4. We probably need indexes on the key columns too:

CREATE INDEX measurement_y2006m02_logdate ON measurement_y2006m02 (logdate);
CREATE INDEX measurement_y2006m03_logdate ON measurement_y2006m03 (logdate);
...
CREATE INDEX measurement_y2007m11_logdate ON measurement_y2007m11 (logdate);
CREATE INDEX measurement_y2007m12_logdate ON measurement_y2007m12 (logdate);
CREATE INDEX measurement_y2008m01_logdate ON measurement_y2008m01 (logdate);

We choose not to add further indexes at this time.

5. We want our application to be able to say INSERT INTO measurement ... and have the data be redirected into the appropriate partition table. We can arrange that by attaching a suitable trigger function to the master table. If data will be added only to the latest partition, we can use a very simple trigger function:

CREATE OR REPLACE FUNCTION measurement_insert_trigger()  
RETURNS TRIGGER AS $$_  
BEGIN
    INSERT INTO measurement_y2008m01 VALUES (NEW.*);
    RETURN NULL;
END;  
$_
LANGUAGE plpgsql;

 After creating the function, we create a trigger which calls the trigger function:

CREATE TRIGGER insert_measurement_trigger
BEFORE INSERT ON measurement
FOR EACH ROW EXECUTE PROCEDURE measurement_insert_trigger();

We must redefine the trigger function each month so that it always points to the current partition. The trigger definition does not need to be updated, however.

We might want to insert data and have the server automatically locate the partition into which the row should be added. We could do this with a more complex trigger function, for example:

CREATE OR REPLACE FUNCTION measurement_insert_trigger()  
RETURNS TRIGGER AS $$_  
BEGIN
    IF ( NEW.logdate >= DATE '2006-02-01' AND NEW.logdate < DATE '2006-03-01' ) THEN
        INSERT INTO measurement_y2006m02 VALUES (NEW.*);
    ELSIF ( NEW.logdate >= DATE '2006-03-01' AND NEW.logdate < DATE '2006-04-01' ) THEN
        INSERT INTO measurement_y2006m03 VALUES (NEW.*);
    ...  
    ELSIF ( NEW.logdate >= DATE '2008-01-01' AND NEW.logdate < DATE '2008-02-01' ) THEN
        INSERT INTO measurement_y2008m01 VALUES (NEW.*);
    ELSE
        RAISE EXCEPTION 'Date out of range. Fix the measurement_insert_trigger() function.';
    END IF;
END;  
$_
LANGUAGE plpgsql;

6. We might want to insert data and have the server automatically locate the partition into which the row should be added. We could do this with a more complex trigger function, for example:
Chapter 5. Data Definition

END IF;
RETURN NULL;
END;
$$
LANGUAGE plpgsql;

The trigger definition is the same as before. Note that each IF test must exactly match the CHECK constraint for its partition.

While this function is more complex than the single-month case, it doesn’t need to be updated as often, since branches can be added in advance of being needed.

Note: In practice it might be best to check the newest partition first, if most inserts go into that partition. For simplicity we have shown the trigger’s tests in the same order as in other parts of this example.

As we can see, a complex partitioning scheme could require a substantial amount of DDL. In the above example we would be creating a new partition each month, so it might be wise to write a script that generates the required DDL automatically.

5.9.3. Managing Partitions

Normally the set of partitions established when initially defining the table are not intended to remain static. It is common to want to remove old partitions of data and periodically add new partitions for new data. One of the most important advantages of partitioning is precisely that it allows this otherwise painful task to be executed nearly instantaneously by manipulating the partition structure, rather than physically moving large amounts of data around.

The simplest option for removing old data is simply to drop the partition that is no longer necessary:

DROP TABLE measurement_y2006m02;

This can very quickly delete millions of records because it doesn’t have to individually delete every record.

Another option that is often preferable is to remove the partition from the partitioned table but retain access to it as a table in its own right:

ALTER TABLE measurement_y2006m02 NO INHERIT measurement;

This allows further operations to be performed on the data before it is dropped. For example, this is often a useful time to back up the data using COPY, pg_dump, or similar tools. It might also be a useful time to aggregate data into smaller formats, perform other data manipulations, or run reports.

Similarly we can add a new partition to handle new data. We can create an empty partition in the partitioned table just as the original partitions were created above:

CREATE TABLE measurement_y2008m02 (  
   CHECK ( logdate >= DATE '2008-02-01' AND logdate < DATE '2008-03-01')  
) INHERITS (measurement);
Chapter 5. Data Definition

As an alternative, it is sometimes more convenient to create the new table outside the partition structure, and make it a proper partition later. This allows the data to be loaded, checked, and transformed prior to it appearing in the partitioned table:

```sql
CREATE TABLE measurement_y2008m02
    (LIKE measurement INCLUDING DEFAULTS INCLUDING CONSTRAINTS);
ALTER TABLE measurement_y2008m02 ADD CONSTRAINT y2008m02
    CHECK (logdate >= DATE '2008-02-01' AND logdate < DATE '2008-03-01');
\copy measurement_y2008m02 from 'measurement_y2008m02'
    -- possibly some other data preparation work
ALTER TABLE measurement_y2008m02 INHERIT measurement;
```

5.9.4. Partitioning and Constraint Exclusion

Constraint exclusion is a query optimization technique that improves performance for partitioned tables defined in the fashion described above. As an example:

```sql
SET constraint_exclusion = on;
SELECT count(*) FROM measurement WHERE logdate >= DATE '2008-01-01';
```

Without constraint exclusion, the above query would scan each of the partitions of the `measurement` table. With constraint exclusion enabled, the planner will examine the constraints of each partition and try to prove that the partition need not be scanned because it could not contain any rows meeting the query’s WHERE clause. When the planner can prove this, it excludes the partition from the query plan.

You can use the `EXPLAIN` command to show the difference between a plan with `constraint_exclusion` on and a plan with it off. A typical default plan for this type of table setup is:

```sql
SET constraint_exclusion = off;
EXPLAIN SELECT count(*) FROM measurement WHERE logdate >= DATE '2008-01-01';
```

```
QUERY PLAN
-----------------------------------------------------------------------------------------------
Aggregate (cost=158.66..158.68 rows=1 width=0)
    -> Append (cost=0.00..151.88 rows=2715 width=0)
        -> Seq Scan on measurement (cost=0.00..30.38 rows=543 width=0)
            Filter: (logdate >= '2008-01-01'::date)
        -> Seq Scan on measurement_y2006m02 measurement (cost=0.00..30.38 rows=543 width=0)
            Filter: (logdate >= '2008-01-01'::date)
        -> Seq Scan on measurement_y2006m03 measurement (cost=0.00..30.38 rows=543 width=0)
            Filter: (logdate >= '2008-01-01'::date)
        ... 
        -> Seq Scan on measurement_y2007m12 measurement (cost=0.00..30.38 rows=543 width=0)
            Filter: (logdate >= '2008-01-01'::date)
        -> Seq Scan on measurement_y2008m01 measurement (cost=0.00..30.38 rows=543 width=0)
            Filter: (logdate >= '2008-01-01'::date)
```

Some or all of the partitions might use index scans instead of full-table sequential scans, but the point here is that there is no need to scan the older partitions at all to answer this query. When we enable constraint exclusion, we get a significantly reduced plan that will deliver the same answer:

```sql
SET constraint_exclusion = on;
```
Chapter 5. Data Definition

EXPLAIN SELECT count(*) FROM measurement WHERE logdate >= DATE '2008-01-01';

QUERY PLAN

Aggregate (cost=63.47..63.48 rows=1 width=0)
   ->  Append (cost=0.00..60.75 rows=1086 width=0)
      ->  Seq Scan on measurement (cost=0.00..30.38 rows=543 width=0)
          Filter: (logdate > '2008-01-01'::date)
      ->  Seq Scan on measurement_y2008m01 measurement (cost=0.00..30.38 rows=543 width=0)
          Filter: (logdate > '2008-01-01'::date)

Note that constraint exclusion is driven only by CHECK constraints, not by the presence of indexes. Therefore it isn’t necessary to define indexes on the key columns. Whether an index needs to be created for a given partition depends on whether you expect that queries that scan the partition will generally scan a large part of the partition or just a small part. An index will be helpful in the latter case but not the former.

5.9.5. Alternative Partitioning Methods

A different approach to redirecting inserts into the appropriate partition table is to set up rules, instead of a trigger, on the master table. For example:

CREATE RULE measurement_insert_y2006m02 AS
ON INSERT TO measurement WHERE
   ( logdate >= DATE '2006-02-01' AND logdate < DATE '2006-03-01' )
DO INSTEAD
   INSERT INTO measurement_y2006m02 VALUES (NEW.*);
...

CREATE RULE measurement_insert_y2008m01 AS
ON INSERT TO measurement WHERE
   ( logdate >= DATE '2008-01-01' AND logdate < DATE '2008-02-01' )
DO INSTEAD
   INSERT INTO measurement_y2008m01 VALUES (NEW.*);

A rule has significantly more overhead than a trigger, but the overhead is paid once per query rather than once per row, so this method might be advantageous for bulk-insert situations. In most cases, however, the trigger method will offer better performance.

Be aware that COPY ignores rules. If you want to use COPY to insert data, you’ll need to copy into the correct partition table rather than into the master. COPY does fire triggers, so you can use it normally if you use the trigger approach.

Another disadvantage of the rule approach is that there is no simple way to force an error if the set of rules doesn’t cover the insertion date; the data will silently go into the master table instead.

Partitioning can also be arranged using a \texttt{UNION ALL} view, instead of table inheritance. For example,

CREATE VIEW measurement AS
   SELECT * FROM measurement_y2006m02
UNION ALL SELECT * FROM measurement_y2006m03
...
UNION ALL SELECT * FROM measurement_y2007m11
UNION ALL SELECT * FROM measurement_y2007m12
UNION ALL SELECT * FROM measurement_y2008m01;
However, the need to recreate the view adds an extra step to adding and dropping individual partitions of the data set. In practice this method has little to recommend it compared to using inheritance.

5.9.6. Caveats

The following caveats apply to partitioned tables:

- There is no automatic way to verify that all of the \texttt{CHECK} constraints are mutually exclusive. It is safer to create code that generates partitions and creates and/or modifies associated objects than to write each by hand.

- The schemes shown here assume that the partition key column(s) of a row never change, or at least do not change enough to require it to move to another partition. An \texttt{UPDATE} that attempts to do that will fail because of the \texttt{CHECK} constraints. If you need to handle such cases, you can put suitable update triggers on the partition tables, but it makes management of the structure much more complicated.

- If you are using manual \texttt{VACUUM} or \texttt{ANALYZE} commands, don’t forget that you need to run them on each partition individually. A command like

  \texttt{ANALYZE measurement;}

  will only process the master table.

The following caveats apply to constraint exclusion:

- Constraint exclusion only works when the query’s \texttt{WHERE} clause contains constants. A parameterized query will not be optimized, since the planner cannot know which partitions the parameter value might select at run time. For the same reason, “stable” functions such as \texttt{CURRENT_DATE} must be avoided.

- Keep the partitioning constraints simple, else the planner may not be able to prove that partitions don’t need to be visited. Use simple equality conditions for list partitioning, or simple range tests for range partitioning, as illustrated in the preceding examples. A good rule of thumb is that partitioning constraints should contain only comparisons of the partitioning column(s) to constants using B-tree-indexable operators.

- All constraints on all partitions of the master table are examined during constraint exclusion, so large numbers of partitions are likely to increase query planning time considerably. Partitioning using these techniques will work well with up to perhaps a hundred partitions; don’t try to use many thousands of partitions.

5.10. Other Database Objects

Tables are the central objects in a relational database structure, because they hold your data. But they are not the only objects that exist in a database. Many other kinds of objects can be created to make the use and management of the data more efficient or convenient. They are not discussed in this chapter, but we give you a list here so that you are aware of what is possible.
5.11. Dependency Tracking

When you create complex database structures involving many tables with foreign key constraints, views, triggers, functions, etc. you will implicitly create a net of dependencies between the objects. For instance, a table with a foreign key constraint depends on the table it references. To ensure the integrity of the entire database structure, PostgreSQL makes sure that you cannot drop objects that other objects still depend on. For example, attempting to drop the products table we had considered in Section 5.3.5, with the orders table depending on it, would result in an error message such as this:

```
DROP TABLE products;
```

```
NOTICE: constraint orders_product_no_fkey on table orders depends on table products
ERROR: cannot drop table products because other objects depend on it
HINT: Use DROP ... CASCADE to drop the dependent objects too.
```

The error message contains a useful hint: if you do not want to bother deleting all the dependent objects individually, you can run

```
DROP TABLE products CASCADE;
```

and all the dependent objects will be removed. In this case, it doesn’t remove the orders table, it only removes the foreign key constraint. (If you want to check what DROP ... CASCADE will do, run DROP without CASCADE and read the NOTICE messages.)

All drop commands in PostgreSQL support specifying CASCADE. Of course, the nature of the possible dependencies varies with the type of the object. You can also write RESTRICT instead of CASCADE to get the default behavior, which is to prevent drops of objects that other objects depend on.

**Note:** According to the SQL standard, specifying either RESTRICT or CASCADE is required. No database system actually enforces that rule, but whether the default behavior is RESTRICT or CASCADE varies across systems.

**Note:** Foreign key constraint dependencies and serial column dependencies from PostgreSQL versions prior to 7.3 are not maintained or created during the upgrade process. All other dependency types will be properly created during an upgrade from a pre-7.3 database.
Chapter 6. Data Manipulation

The previous chapter discussed how to create tables and other structures to hold your data. Now it is time to fill the tables with data. This chapter covers how to insert, update, and delete table data. We also introduce ways to effect automatic data changes when certain events occur: triggers and rewrite rules. The chapter after this will finally explain how to extract your long-lost data back out of the database.

6.1. Inserting Data

When a table is created, it contains no data. The first thing to do before a database can be of much use is to insert data. Data is conceptually inserted one row at a time. Of course you can also insert more than one row, but there is no way to insert less than one row at a time. Even if you know only some column values, a complete row must be created.

To create a new row, use the INSERT command. The command requires the table name and a value for each of the columns of the table. For example, consider the products table from Chapter 5:

```
CREATE TABLE products {
    product_no integer,
    name text,
    price numeric
};
```

An example command to insert a row would be:

```
INSERT INTO products VALUES (1, 'Cheese', 9.99);
```

The data values are listed in the order in which the columns appear in the table, separated by commas. Usually, the data values will be literals (constants), but scalar expressions are also allowed.

The above syntax has the drawback that you need to know the order of the columns in the table. To avoid that you can also list the columns explicitly. For example, both of the following commands have the same effect as the one above:

```
INSERT INTO products (product_no, name, price) VALUES (1, 'Cheese', 9.99);
INSERT INTO products (name, price, product_no) VALUES ('Cheese', 9.99, 1);
```

Many users consider it good practice to always list the column names.

If you don’t have values for all the columns, you can omit some of them. In that case, the columns will be filled with their default values. For example:

```
INSERT INTO products (product_no, name) VALUES (1, 'Cheese');
INSERT INTO products VALUES (1, 'Cheese');
```

The second form is a PostgreSQL extension. It fills the columns from the left with as many values as are given, and the rest will be defaulted.

For clarity, you can also request default values explicitly, for individual columns or for the entire row:

```
INSERT INTO products (product_no, name, price) VALUES (1, 'Cheese', DEFAULT);
INSERT INTO products DEFAULT VALUES;
```
You can insert multiple rows in a single command:

```
INSERT INTO products (product_no, name, price) VALUES
  (1, 'Cheese', 9.99),
  (2, 'Bread', 1.99),
  (3, 'Milk', 2.99);
```

**Tip:** When inserting a lot of data at the same time, considering using the `COPY` command. It is not as flexible as the `INSERT` command, but is more efficient. Refer to Section 14.4 for more information on improving bulk loading performance.

### 6.2. Updating Data

The modification of data that is already in the database is referred to as updating. You can update individual rows, all the rows in a table, or a subset of all rows. Each column can be updated separately; the other columns are not affected.

To perform an update, you need three pieces of information:

1. The name of the table and column to update,
2. The new value of the column,
3. Which row(s) to update.

Recall from Chapter 5 that SQL does not, in general, provide a unique identifier for rows. Therefore it is not necessarily possible to directly specify which row to update. Instead, you specify which conditions a row must meet in order to be updated. Only if you have a primary key in the table (no matter whether you declared it or not) can you reliably address individual rows, by choosing a condition that matches the primary key. Graphical database access tools rely on this fact to allow you to update rows individually.

For example, this command updates all products that have a price of 5 to have a price of 10:

```
UPDATE products SET price = 10 WHERE price = 5;
```

This might cause zero, one, or many rows to be updated. It is not an error to attempt an update that does not match any rows.

Let’s look at that command in detail. First is the key word `UPDATE` followed by the table name. As usual, the table name can be schema-qualified, otherwise it is looked up in the path. Next is the key word `SET` followed by the column name, an equals sign and the new column value. The new column value can be any scalar expression, not just a constant. For example, if you want to raise the price of all products by 10% you could use:

```
UPDATE products SET price = price * 1.10;
```

As you see, the expression for the new value can refer to the existing value(s) in the row. We also left out the `WHERE` clause. If it is omitted, it means that all rows in the table are updated. If it is present, only those rows that match the `WHERE` condition are updated. Note that the equals sign in the `SET` clause is an assignment while the one in the `WHERE` clause is a comparison, but this does not
create any ambiguity. Of course, the WHERE condition does not have to be an equality test. Many other operators are available (see Chapter 9). But the expression needs to evaluate to a Boolean result.

You can update more than one column in an UPDATE command by listing more than one assignment in the SET clause. For example:

```
UPDATE mytable SET a = 5, b = 3, c = 1 WHERE a > 0;
```

6.3. Deleting Data

So far we have explained how to add data to tables and how to change data. What remains is to discuss how to remove data that is no longer needed. Just as adding data is only possible in whole rows, you can only remove entire rows from a table. In the previous section we explained that SQL does not provide a way to directly address individual rows. Therefore, removing rows can only be done by specifying conditions that the rows to be removed have to match. If you have a primary key in the table then you can specify the exact row. But you can also remove groups of rows matching a condition, or you can remove all rows in the table at once.

You use the DELETE command to remove rows; the syntax is very similar to the UPDATE command. For instance, to remove all rows from the products table that have a price of 10, use:

```
DELETE FROM products WHERE price = 10;
```

If you simply write:

```
DELETE FROM products;
```

then all rows in the table will be deleted! Caveat programmer.
Chapter 7. Queries

The previous chapters explained how to create tables, how to fill them with data, and how to manipulate that data. Now we finally discuss how to retrieve the data out of the database.

7.1. Overview

The process of retrieving or the command to retrieve data from a database is called a query. In SQL the SELECT command is used to specify queries. The general syntax of the SELECT command is

```
SELECT select_list FROM table_expression [sort_specification]
```

The following sections describe the details of the select list, the table expression, and the sort specification.

A simple kind of query has the form:

```
SELECT * FROM table1;
```

Assuming that there is a table called `table1`, this command would retrieve all rows and all columns from `table1`. (The method of retrieval depends on the client application. For example, the psql program will display an ASCII-art table on the screen, while client libraries will offer functions to extract individual values from the query result.) The select list specification `*` means all columns that the table expression happens to provide. A select list can also select a subset of the available columns or make calculations using the columns. For example, if `table1` has columns named `a`, `b`, and `c` (and perhaps others) you can make the following query:

```
SELECT a, b + c FROM table1;
```

(assuming that `b` and `c` are of a numerical data type). See Section 7.3 for more details.

```
FROM table1 is a particularly simple kind of table expression: it reads just one table. In general, table expressions can be complex constructs of base tables, joins, and subqueries. But you can also omit the table expression entirely and use the SELECT command as a calculator:
```

```
SELECT 3 * 4;
```

This is more useful if the expressions in the select list return varying results. For example, you could call a function this way:

```
SELECT random();
```

7.2. Table Expressions

A table expression computes a table. The table expression contains a FROM clause that is optionally followed by WHERE, GROUP BY, and HAVING clauses. Trivial table expressions simply refer to a table on disk, a so-called base table, but more complex expressions can be used to modify or combine base tables in various ways.

The optional WHERE, GROUP BY, and HAVING clauses in the table expression specify a pipeline of successive transformations performed on the table derived in the FROM clause. All these transforma-
tions produce a virtual table that provides the rows that are passed to the select list to compute the output rows of the query.

## 7.2.1. The FROM Clause

The **FROM Clause** derives a table from one or more other tables given in a comma-separated table reference list.

```sql
FROM table_reference [, table_reference [, ...]]
```

A table reference can be a table name (possibly schema-qualified), or a derived table such as a sub-query, a table join, or complex combinations of these. If more than one table reference is listed in the `FROM` clause they are cross-joined (see below) to form the intermediate virtual table that can then be subject to transformations by the `WHERE`, `GROUP BY`, and `HAVING` clauses and is finally the result of the overall table expression.

When a table reference names a table that is the parent of a table inheritance hierarchy, the table reference produces rows of not only that table but all of its descendant tables, unless the key word `ONLY` precedes the table name. However, the reference produces only the columns that appear in the named table — any columns added in subtables are ignored.

Instead of writing `ONLY` before the table name, you can write `*` after the table name to explicitly specify that descendant tables are included. Writing `*` is not necessary since that behavior is the default (unless you have changed the setting of the `sql_inheritance` configuration option). However writing `*` might be useful to emphasize that additional tables will be searched.

### 7.2.1.1. Joined Tables

A joined table is a table derived from two other (real or derived) tables according to the rules of the particular join type. Inner, outer, and cross-joins are available.

#### Join Types

**Cross join**

```sql
T1 CROSS JOIN T2
```

For each combination of rows from `T1` and `T2`, the derived table will contain a row consisting of all columns in `T1` followed by all columns in `T2`. If the tables have N and M rows respectively, the joined table will have N * M rows.

```sql
FROM T1 CROSS JOIN T2
```

is equivalent to `FROM T1, T2`. It is also equivalent to `FROM T1 INNER JOIN T2 ON TRUE` (see below).

**Qualified joins**

```sql
T1 { [INNER] | { LEFT | RIGHT | FULL } [OUTER] } JOIN T2 ON boolean_expression
T1 { [INNER] | { LEFT | RIGHT | FULL } [OUTER] } JOIN T2 USING ( join column list )
T1 NATURAL { [INNER] | { LEFT | RIGHT | FULL } [OUTER] } JOIN T2
```

The words **INNER** and **OUTER** are optional in all forms. **INNER** is the default; **LEFT**, **RIGHT**, and **FULL** imply an outer join.

The **join condition** is specified in the `ON` or `USING` clause, or implicitly by the word `NATURAL`. The join condition determines which rows from the two source tables are considered to “match”, as explained in detail below.
Chapter 7. Queries

The **ON** clause is the most general kind of join condition: it takes a Boolean value expression of the same kind as is used in a **WHERE** clause. A pair of rows from \( T1 \) and \( T2 \) match if the **ON** expression evaluates to true for them.

**USING** is a shorthand notation: it takes a comma-separated list of column names, which the joined tables must have in common, and forms a join condition specifying equality of each of these pairs of columns. Furthermore, the output of a **JOIN USING** has one column for each of the equated pairs of input columns, followed by all of the other columns from each table. Thus, **USING** \((a, b, c)\) is equivalent to **ON** \((t1.a = t2.a \text{ AND } t1.b = t2.b \text{ AND } t1.c = t2.c)\) with the exception that if **ON** is used there will be two columns \(a, b, \text{ and } c\) in the result, whereas with **USING** there will be only one of each.

Finally, **NATURAL** is a shorthand form of **USING**: it forms a **USING** list consisting of exactly those column names that appear in both input tables. As with **USING**, these columns appear only once in the output table.

The possible types of qualified join are:

**INNER JOIN**

For each row \( R1 \) of \( T1 \), the joined table has a row for each row in \( T2 \) that satisfies the join condition with \( R1 \).

**LEFT OUTER JOIN**

First, an inner join is performed. Then, for each row in \( T1 \) that does not satisfy the join condition with any row in \( T2 \), a joined row is added with null values in columns of \( T2 \). Thus, the joined table unconditionally has at least one row for each row in \( T1 \).

**RIGHT OUTER JOIN**

First, an inner join is performed. Then, for each row in \( T2 \) that does not satisfy the join condition with any row in \( T1 \), a joined row is added with null values in columns of \( T1 \). This is the converse of a left join: the result table will unconditionally have a row for each row in \( T2 \).

**FULL OUTER JOIN**

First, an inner join is performed. Then, for each row in \( T1 \) that does not satisfy the join condition with any row in \( T2 \), a joined row is added with null values in columns of \( T2 \). Also, for each row of \( T2 \) that does not satisfy the join condition with any row in \( T1 \), a joined row with null values in the columns of \( T1 \) is added.

Joins of all types can be chained together or nested: either or both of \( T1 \) and \( T2 \) might be joined tables. Parentheses can be used around **JOIN** clauses to control the join order. In the absence of parentheses, **JOIN** clauses nest left-to-right.

To put this together, assume we have tables \( t1 \):

```
<table>
<thead>
<tr>
<th>num</th>
<th>name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a</td>
</tr>
<tr>
<td>2</td>
<td>b</td>
</tr>
<tr>
<td>3</td>
<td>c</td>
</tr>
</tbody>
</table>
```

and \( t2 \):

```
<table>
<thead>
<tr>
<th>num</th>
<th>value</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>------</td>
</tr>
</tbody>
</table>
```

74
then we get the following results for the various joins:

```sql
-> SELECT * FROM t1 CROSS JOIN t2;
num | name | num | value
-----+------+-----+-------
 1   | a    | 1   | xxx   
 1   | a    | 3   | yyy   
 1   | a    | 5   | zzz   
 2   | b    | 1   | xxx   
 2   | b    | 3   | yyy   
 2   | b    | 5   | zzz   
 3   | c    | 1   | xxx   
 3   | c    | 3   | yyy   
 3   | c    | 5   | zzz   
(9 rows)
```

```sql
-> SELECT * FROM t1 INNER JOIN t2 ON t1.num = t2.num;
num | name | num | value
-----+------+-----+-------
 1   | a    | 1   | xxx   
 3   | c    | 3   | yyy   
(2 rows)
```

```sql
-> SELECT * FROM t1 INNER JOIN t2 USING (num);
num | name | value
-----+------+-------
 1   | a    | xxx   
 3   | c    | yyy   
(2 rows)
```

```sql
-> SELECT * FROM t1 NATURAL INNER JOIN t2;
num | name | value
-----+------+-------
 1   | a    | xxx   
 3   | c    | yyy   
(2 rows)
```

```sql
-> SELECT * FROM t1 LEFT JOIN t2 ON t1.num = t2.num;
num | name | num | value
-----+------+-----+-------
 1   | a    | 1   | xxx   
 2   | b    |     |       
 3   | c    | 3   | yyy   
(3 rows)
```

```sql
-> SELECT * FROM t1 LEFT JOIN t2 USING (num);
num | name | value
-----+------+-------
 1   | a    | xxx   
 2   | b    |       
 3   | c    | yyy   
(3 rows)
```
The join condition specified with ON can also contain conditions that do not relate directly to the join. This can prove useful for some queries but needs to be thought out carefully. For example:

```sql
-> SELECT * FROM t1 LEFT JOIN t2 ON t1.num = t2.num AND t2.value = 'xxx';
```

<table>
<thead>
<tr>
<th>num</th>
<th>name</th>
<th>num</th>
<th>value</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a</td>
<td>1</td>
<td>xxx</td>
</tr>
<tr>
<td>2</td>
<td>b</td>
<td></td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>c</td>
<td>3</td>
<td>yyy</td>
</tr>
<tr>
<td></td>
<td></td>
<td>5</td>
<td>zzz</td>
</tr>
</tbody>
</table>

(3 rows)

7.2.1.2. Table and Column Aliases

A temporary name can be given to tables and complex table references to be used for references to the derived table in the rest of the query. This is called a **table alias**.

To create a table alias, write

```
FROM table_reference AS alias
```

or

```
FROM table_reference alias
```

The **AS** key word is noise. **alias** can be any identifier.

A typical application of table aliases is to assign short identifiers to long table names to keep the join clauses readable. For example:

```
SELECT * FROM some_very_long_table_name s JOIN another_fairly_long_name a ON s.id = a.num
```

The alias becomes the new name of the table reference for the current query — it is no longer possible to refer to the table by the original name. Thus:

```
SELECT * FROM my_table AS m WHERE my_table.a > 5;
```
is not valid according to the SQL standard. In PostgreSQL this will draw an error if the add_missing_from configuration variable is off (as it is by default). If it is on, an implicit table reference will be added to the FROM clause, so the query is processed as if it were written as:

```sql
SELECT * FROM my_table AS m, my_table AS my_table WHERE my_table.a > 5;
```

That will result in a cross join, which is usually not what you want.

Table aliases are mainly for notational convenience, but it is necessary to use them when joining a table to itself, e.g.:

```sql
SELECT * FROM people AS mother JOIN people AS child ON mother.id = child.mother_id;
```

Additionally, an alias is required if the table reference is a subquery (see Section 7.2.1.3).

Parentheses are used to resolve ambiguities. In the following example, the first statement assigns the alias b to the second instance of my_table, but the second statement assigns the alias to the result of the join:

```sql
SELECT * FROM my_table AS a CROSS JOIN my_table AS b ...
SELECT * FROM (my_table AS a CROSS JOIN my_table) AS b ...
```

Another form of table aliasing gives temporary names to the columns of the table, as well as the table itself:

```sql
FROM table_reference [AS] alias ( column1 [, column2 [, ...]] )
```

If fewer column aliases are specified than the actual table has columns, the remaining columns are not renamed. This syntax is especially useful for self-joins or subqueries.

When an alias is applied to the output of a JOIN clause, using any of these forms, the alias hides the original names within the JOIN. For example:

```sql
SELECT a.* FROM my_table AS a JOIN your_table AS b ON ...
```

is valid SQL, but:

```sql
SELECT a.* FROM (my_table AS a JOIN your_table AS b ON ...) AS c
```

is not valid: the table alias a is not visible outside the alias c.

### 7.2.1.3. Subqueries

Subqueries specifying a derived table must be enclosed in parentheses and must be assigned a table alias name. (See Section 7.2.1.2.) For example:

```sql
FROM (SELECT * FROM table1) AS alias_name
```

This example is equivalent to `FROM table1 AS alias_name`. More interesting cases, which cannot be reduced to a plain join, arise when the subquery involves grouping or aggregation.

A subquery can also be a VALUES list:

```sql
FROM (VALUES ('anne', 'smith'), ('bob', 'jones'), ('joe', 'blow')) AS names(first, last)
```
Again, a table alias is required. Assigning alias names to the columns of the VALUES list is optional, but is good practice. For more information see Section 7.7.

7.2.1.4. Table Functions

Table functions are functions that produce a set of rows, made up of either base data types (scalar types) or composite data types (table rows). They are used like a table, view, or subquery in the FROM clause of a query. Columns returned by table functions can be included in SELECT, JOIN, or WHERE clauses in the same manner as a table, view, or subquery column.

If a table function returns a base data type, the single result column is named like the function. If the function returns a composite type, the result columns get the same names as the individual attributes of the type.

A table function can be aliased in the FROM clause, but it also can be left unaliased. If a function is used in the FROM clause with no alias, the function name is used as the resulting table name.

Some examples:

```sql
CREATE TABLE foo (fooid int, foosubid int, fooname text);

CREATE FUNCTION getfoo(int) RETURNS SETOF foo AS $$
SELECT * FROM foo WHERE fooid = $1;
$$ LANGUAGE SQL;

SELECT * FROM getfoo(1) AS t1;

SELECT * FROM foo
WHERE foosubid IN (select foosubid from getfoo(foo.fooid) z
where z.fooid = foo.fooid);

CREATE VIEW vw_getfoo AS SELECT * FROM getfoo(1);

SELECT * FROM vw_getfoo;
```

In some cases it is useful to define table functions that can return different column sets depending on how they are invoked. To support this, the table function can be declared as returning the pseudotype record. When such a function is used in a query, the expected row structure must be specified in the query itself, so that the system can know how to parse and plan the query. Consider this example:

```sql
SELECT *
FROM dblink('dbname=mydb', 'select proname, prosrc from pg_proc')
AS t1(proname name, prosrc text)
WHERE proname LIKE 'bytea%';
```

The dblink function executes a remote query (see contrib/dblink). It is declared to return record since it might be used for any kind of query. The actual column set must be specified in the calling query so that the parser knows, for example, what * should expand to.
7.2.2. The WHERE Clause

The syntax of the WHERE Clause is

```
WHERE search_condition
```

where `search_condition` is any value expression (see Section 4.2) that returns a value of type boolean.

After the processing of the FROM clause is done, each row of the derived virtual table is checked against the search condition. If the result of the condition is true, the row is kept in the output table, otherwise (that is, if the result is false or null) it is discarded. The search condition typically references at least some column of the table generated in the FROM clause; this is not required, but otherwise the WHERE clause will be fairly useless.

**Note:** The join condition of an inner join can be written either in the WHERE clause or in the JOIN clause. For example, these table expressions are equivalent:

```
FROM a, b WHERE a.id = b.id AND b.val > 5
```

and:

```
FROM a INNER JOIN b ON (a.id = b.id) WHERE b.val > 5
```

or perhaps even:

```
FROM a NATURAL JOIN b WHERE b.val > 5
```

Which one of these you use is mainly a matter of style. The JOIN syntax in the FROM clause is probably not as portable to other SQL database management systems. For outer joins there is no choice in any case: they must be done in the FROM clause. An ON/USING clause of an outer join is not equivalent to a WHERE condition, because it determines the addition of rows (for unmatched input rows) as well as the removal of rows from the final result.

Here are some examples of WHERE clauses:

```
SELECT ... FROM fdt WHERE c1 > 5
SELECT ... FROM fdt WHERE c1 IN (1, 2, 3)
SELECT ... FROM fdt WHERE c1 IN (SELECT c1 FROM t2)
SELECT ... FROM fdt WHERE c1 IN (SELECT c3 FROM t2 WHERE c2 = fdt.c1 + 10)
SELECT ... FROM fdt WHERE c1 BETWEEN (SELECT c3 FROM t2 WHERE c2 = fdt.c1 + 10) AND 100
SELECT ... FROM fdt WHERE EXISTS (SELECT c1 FROM t2 WHERE c2 > fdt.c1)
```

`fdt` is the table derived in the FROM clause. Rows that do not meet the search condition of the WHERE clause are eliminated from `fdt`. Notice the use of scalar subqueries as value expressions. Just like any other query, the subqueries can employ complex table expressions. Notice also how `fdt` is referenced in the subqueries. Qualifying `c1` as `fdt.c1` is only necessary if `c1` is also the name of a column in the derived input table of the subquery. But qualifying the column name adds clarity even when it is not needed. This example shows how the column naming scope of an outer query extends into its inner queries.
7.2.3. The \textit{GROUP BY} and \textit{HAVING} Clauses

After passing the \textit{WHERE} filter, the derived input table might be subject to grouping, using the \textit{GROUP BY} clause, and elimination of group rows using the \textit{HAVING} clause.

\begin{verbatim}
SELECT select_list
    FROM ...
    [WHERE ...]
    GROUP BY grouping_column_reference [, grouping_column_reference]...
\end{verbatim}

The \textit{GROUP BY} Clause is used to group together those rows in a table that share the same values in all the columns listed. The order in which the columns are listed does not matter. The effect is to combine each set of rows sharing common values into one group row that is representative of all rows in the group. This is done to eliminate redundancy in the output and/or compute aggregates that apply to these groups. For instance:

\begin{verbatim}
=> SELECT * FROM test1;
x | y
---+---
a | 3
b | 5
c | 2
a | 1
(4 rows)
=> SELECT x FROM test1 GROUP BY x;
x
---
a b c
(3 rows)
\end{verbatim}

In the second query, we could not have written \texttt{SELECT * FROM test1 GROUP BY x}, because there is no single value for the column \textit{y} that could be associated with each group. The grouped-by columns can be referenced in the select list since they have a single value in each group.

In general, if a table is grouped, columns that are not used in the grouping cannot be referenced except in aggregate expressions. An example with aggregate expressions is:

\begin{verbatim}
=> SELECT x, sum(y) FROM test1 GROUP BY x;
x | sum
---+-----
a | 4   
b | 5   
c | 2   
(3 rows)
\end{verbatim}

Here \texttt{sum} is an aggregate function that computes a single value over the entire group. More information about the available aggregate functions can be found in Section 9.18.

\textbf{Tip:} Grouping without aggregate expressions effectively calculates the set of distinct values in a column. This can also be achieved using the \texttt{DISTINCT} clause (see Section 7.3.3).
Here is another example: it calculates the total sales for each product (rather than the total sales on all products):

```sql
SELECT product_id, p.name, (sum(s.units) * p.price) AS sales
FROM products p LEFT JOIN sales s USING (product_id)
GROUP BY product_id, p.name, p.price;
```

In this example, the columns `product_id`, `p.name`, and `p.price` must be in the `GROUP BY` clause since they are referenced in the query select list. (Depending on how exactly the products table is set up, name and price might be fully dependent on the product ID, so the additional groupings could theoretically be unnecessary, but this is not implemented yet.) The column `s.units` does not have to be in the `GROUP BY` list since it is only used in an aggregate expression (`sum(...)`), which represents the sales of a product. For each product, the query returns a summary row about all sales of the product.

In strict SQL, `GROUP BY` can only group by columns of the source table but PostgreSQL extends this to also allow `GROUP BY` to group by columns in the select list. Grouping by value expressions instead of simple column names is also allowed.

If a table has been grouped using a `GROUP BY` clause, but then only certain groups are of interest, the `HAVING` clause can be used, much like a `WHERE` clause, to eliminate groups from a grouped table. The syntax is:

```sql
SELECT select_list FROM ... [WHERE ...] GROUP BY ... HAVING boolean_expression
```

Expressions in the `HAVING` clause can refer both to grouped expressions and to ungrouped expressions (which necessarily involve an aggregate function).

Example:

```sql
--> SELECT x, sum(y) FROM test1 GROUP BY x HAVING sum(y) > 3;
 x | sum  
---+-----
a |  4   
b |  5   
(2 rows)

--> SELECT x, sum(y) FROM test1 GROUP BY x HAVING x < 'c';
 x | sum  
---+-----
a |  4   
b |  5   
(2 rows)
```

Again, a more realistic example:

```sql
SELECT product_id, p.name, (sum(s.units) * (p.price - p.cost)) AS profit
FROM products p LEFT JOIN sales s USING (product_id)
WHERE s.date > CURRENT_DATE - INTERVAL '4 weeks'
GROUP BY product_id, p.name, p.price, p.cost
HAVING sum(p.price * s.units) > 5000;
```

In the example above, the `WHERE` clause is selecting rows by a column that is not grouped (the expression is only true for sales during the last four weeks), while the `HAVING` clause restricts the output to groups with total gross sales over 5000. Note that the aggregate expressions do not necessarily need to be the same in all parts of the query.
7.3. Select Lists

As shown in the previous section, the table expression in the SELECT command constructs an intermediate virtual table by possibly combining tables, views, eliminating rows, grouping, etc. This table is finally passed on to processing by the select list. The select list determines which columns of the intermediate table are actually output.

7.3.1. Select-List Items

The simplest kind of select list is * which emits all columns that the table expression produces. Otherwise, a select list is a comma-separated list of value expressions (as defined in Section 4.2). For instance, it could be a list of column names:

```
SELECT a, b, c FROM ...  
```

The columns names a, b, and c are either the actual names of the columns of tables referenced in the FROM clause, or the aliases given to them as explained in Section 7.2.1.2. The name space available in the select list is the same as in the WHERE clause, unless grouping is used, in which case it is the same as in the HAVING clause.

If more than one table has a column of the same name, the table name must also be given, as in:

```
SELECT tbl1.a, tbl2.a, tbl1.b FROM ...  
```

When working with multiple tables, it can also be useful to ask for all the columns of a particular table:

```
SELECT tbl1.*, tbl2.a FROM ...  
```

(See also Section 7.2.2.)

If an arbitrary value expression is used in the select list, it conceptually adds a new virtual column to the returned table. The value expression is evaluated once for each result row, with the row’s values substituted for any column references. But the expressions in the select list do not have to reference any columns in the table expression of the FROM clause; they could be constant arithmetic expressions as well, for instance.

7.3.2. Column Labels

The entries in the select list can be assigned names for further processing. The “further processing” in this case is an optional sort specification and the client application (e.g., column headers for display). For example:

```
SELECT a AS value, b + c AS sum FROM ...  
```

If no output column name is specified using AS, the system assigns a default name. For simple column references, this is the name of the referenced column. For function calls, this is the name of the function. For complex expressions, the system will generate a generic name.

Note: The naming of output columns here is different from that done in the FROM clause (see Section 7.2.1.2). This pipeline will in fact allow you to rename the same column twice, but the name chosen in the select list is the one that will be passed on.
7.3.3. DISTINCT

After the select list has been processed, the result table can optionally be subject to the elimination of duplicate rows. The **DISTINCT** key word is written directly after **SELECT** to specify this:

```sql
SELECT DISTINCT select_list ...
```

(Instead of **DISTINCT** the key word **ALL** can be used to specify the default behavior of retaining all rows.)

Obviously, two rows are considered distinct if they differ in at least one column value. Null values are considered equal in this comparison.

Alternatively, an arbitrary expression can determine what rows are to be considered distinct:

```sql
SELECT DISTINCT ON (expression [, expression ...]) select_list ...
```

Here **expression** is an arbitrary value expression that is evaluated for all rows. A set of rows for which all the expressions are equal are considered duplicates, and only the first row of the set is kept in the output. Note that the “first row” of a set is unpredictable unless the query is sorted on enough columns to guarantee a unique ordering of the rows arriving at the **DISTINCT** filter. (**DISTINCT ON processing occurs after ORDER BY sorting.**) The **DISTINCT ON** clause is not part of the SQL standard and is sometimes considered bad style because of the potentially indeterminate nature of its results. With judicious use of **GROUP BY** and subqueries in **FROM** the construct can be avoided, but it is often the most convenient alternative.

7.4. Combining Queries

The results of two queries can be combined using the set operations union, intersection, and difference. The syntax is

```sql
query1 UNION [ALL] query2
query1 INTERSECT [ALL] query2
query1 EXCEPT [ALL] query2
```

**query1** and **query2** are queries that can use any of the features discussed up to this point. Set operations can also be nested and chained, for example

```sql
query1 UNION query2 UNION query3
```

which really says

```sql
(query1 UNION query2) UNION query3
```

**UNION** effectively appends the result of **query2** to the result of **query1** (although there is no guarantee that this is the order in which the rows are actually returned). Furthermore, it eliminates duplicate rows from its result, in the same way as **DISTINCT**, unless **UNION ALL** is used.
Chapter 7. Queries

INTERSECT returns all rows that are both in the result of \textit{query1} and in the result of \textit{query2}. Duplicate rows are eliminated unless \texttt{INTERSECT ALL} is used.

EXCEPT returns all rows that are in the result of \textit{query1} but not in the result of \textit{query2}. (This is sometimes called the \textit{difference} between two queries.) Again, duplicates are eliminated unless \texttt{EXCEPT ALL} is used.

In order to calculate the union, intersection, or difference of two queries, the two queries must be “union compatible”, which means that they return the same number of columns and the corresponding columns have compatible data types, as described in Section 10.5.

7.5. Sorting Rows

After a query has produced an output table (after the select list has been processed) it can optionally be sorted. If sorting is not chosen, the rows will be returned in an unspecified order. The actual order in that case will depend on the scan and join plan types and the order on disk, but it must not be relied on. A particular output ordering can only be guaranteed if the sort step is explicitly chosen.

The \texttt{ORDER BY} clause specifies the sort order:

\begin{verbatim}
SELECT select_list
  FROM table_expression
  ORDER BY sort_expression1 [ASC | DESC] [NULLS { FIRST | LAST }]
    [, sort_expression2 [ASC | DESC] [NULLS { FIRST | LAST }] ...]
\end{verbatim}

The sort expression(s) can be any expression that would be valid in the query’s select list. An example is:

\begin{verbatim}
SELECT a, b FROM table1 ORDER BY a + b, c;
\end{verbatim}

When more than one expression is specified, the later values are used to sort rows that are equal according to the earlier values. Each expression can be followed by an optional \texttt{ASC} or \texttt{DESC} keyword to set the sort direction to ascending or descending. \texttt{ASC} order is the default. Ascending order puts smaller values first, where “smaller” is defined in terms of the \texttt{<} operator. Similarly, descending order is determined with the \texttt{>} operator.\footnote{Actually, PostgreSQL uses the \textit{default B-tree operator class} for the expression’s data type to determine the sort ordering for \texttt{ASC} and \texttt{DESC}. Conventionally, data types will be set up so that the \texttt{<} and \texttt{>} operators correspond to this sort ordering, but a user-defined data type’s designer could choose to do something different.}

The \texttt{NULLS FIRST} and \texttt{NULLS LAST} options can be used to determine whether nulls appear before or after non-null values in the sort ordering. By default, null values sort as if larger than any non-null value; that is, \texttt{NULLS FIRST} is the default for \texttt{DESC} order, and \texttt{NULLS LAST} otherwise.

Note that the ordering options are considered independently for each sort column. For example \texttt{ORDER BY x, y DESC} means \texttt{ORDER BY x ASC, y DESC}, which is not the same as \texttt{ORDER BY x DESC, y DESC}.

For backwards compatibility with the SQL92 version of the standard, a sort expression can instead be the name or number of an output column, as in:

\begin{verbatim}
SELECT a + b AS sum, c FROM table1 ORDER BY sum;
SELECT a, max(b) FROM table1 GROUP BY a ORDER BY 1;
\end{verbatim}

both of which sort by the first output column. Note that an output column name has to stand alone, it’s not allowed as part of an expression — for example, this is \textit{not} correct:
SELECT a + b AS sum, c FROM table1 ORDER BY sum + c; -- wrong

This restriction is made to reduce ambiguity. There is still ambiguity if an ORDER BY item is a simple name that could match either an output column name or a column from the table expression. The output column is used in such cases. This would only cause confusion if you use AS to rename an output column to match some other table column's name.

ORDER BY can be applied to the result of a UNION, INTERSECT, or EXCEPT combination, but in this case it is only permitted to sort by output column names or numbers, not by expressions.

7.6. LIMIT and OFFSET

LIMIT and OFFSET allow you to retrieve just a portion of the rows that are generated by the rest of the query:

```
SELECT select_list
FROM table_expression
[ ORDER BY ... ]
[ LIMIT { number | ALL } ] [ OFFSET number ]
```

If a limit count is given, no more than that many rows will be returned (but possibly less, if the query itself yields less rows). LIMIT ALL is the same as omitting the LIMIT clause.

OFFSET says to skip that many rows before beginning to return rows. OFFSET 0 is the same as omitting the OFFSET clause. If both OFFSET and LIMIT appear, then OFFSET rows are skipped before starting to count the LIMIT rows that are returned.

When using LIMIT, it is important to use an ORDER BY clause that constrains the result rows into a unique order. Otherwise you will get an unpredictable subset of the query’s rows. You might be asking for the tenth through twentieth rows, but tenth through twentieth in what ordering? The ordering is unknown, unless you specified ORDER BY.

The query optimizer takes LIMIT into account when generating a query plan, so you are very likely to get different plans (yielding different row orders) depending on what you give for LIMIT and OFFSET. Thus, using different LIMIT/OFFSET values to select different subsets of a query result will give inconsistent results unless you enforce a predictable result ordering with ORDER BY. This is not a bug; it is an inherent consequence of the fact that SQL does not promise to deliver the results of a query in any particular order unless ORDER BY is used to constrain the order.

The rows skipped by an OFFSET clause still have to be computed inside the server; therefore a large OFFSET might be inefficient.

7.7. VALUES Lists

VALUES provides a way to generate a “constant table” that can be used in a query without having to actually create and populate a table on-disk. The syntax is

```
VALUES ( expression [, ...] ) [, ...]
```

Each parenthesized list of expressions generates a row in the table. The lists must all have the same number of elements (i.e., the number of columns in the table), and corresponding entries in each
list must have compatible data types. The actual data type assigned to each column of the result is determined using the same rules as for \texttt{UNION} (see Section 10.5).

As an example:

\texttt{VALUES (1, ’one’), (2, ’two’), (3, ’three’);}

will return a table of two columns and three rows. It’s effectively equivalent to:

\begin{verbatim}
SELECT 1 AS column1, ’one’ AS column2
UNION ALL
SELECT 2, ’two’
UNION ALL
SELECT 3, ’three’;
\end{verbatim}

By default, PostgreSQL assigns the names \texttt{column1}, \texttt{column2}, etc. to the columns of a \texttt{VALUES} table. The column names are not specified by the SQL standard and different database systems do it differently, so it’s usually better to override the default names with a table alias list.

Syntactically, \texttt{VALUES} followed by expression lists is treated as equivalent to

\begin{verbatim}
SELECT select_list FROM expression
\end{verbatim}

and can appear anywhere a \texttt{SELECT} can. For example, you can use it as an arm of a \texttt{UNION}, or attach a \texttt{sort_specification} (\texttt{ORDER BY}, \texttt{LIMIT}, and/or \texttt{OFFSET}) to it. \texttt{VALUES} is most commonly used as the data source in an \texttt{INSERT} command, and next most commonly as a subquery.

For more information see \texttt{VALUES}.
Chapter 8. Data Types

PostgreSQL has a rich set of native data types available to users. Users can add new types to PostgreSQL using the `CREATE TYPE` command.

Table 8-1 shows all the built-in general-purpose data types. Most of the alternative names listed in the “Aliases” column are the names used internally by PostgreSQL for historical reasons. In addition, some internally used or deprecated types are available, but they are not listed here.

<table>
<thead>
<tr>
<th>Name</th>

Compatibility: The following types (or spellings thereof) are specified by SQL: bigint, bit, bit varying, boolean, char, character varying, character, varchar, date, double precision, integer, interval, numeric, decimal, real, smallint, time (with or without time zone), timestamp (with or without time zone), xml.

Each data type has an external representation determined by its input and output functions. Many of the built-in types have obvious external formats. However, several types are either unique to PostgreSQL, such as geometric paths, or have several possibilities for formats, such as the date and time types. Some of the input and output functions are not invertible. That is, the result of an output function might lose accuracy when compared to the original input.

8.1. Numeric Types

Numeric types consist of two-, four-, and eight-byte integers, four- and eight-byte floating-point numbers, and selectable-precision decimals. Table 8-2 lists the available types.

Table 8-2. Numeric Types

</tr>
</tbody>
</table>
The syntax of constants for the numeric types is described in Section 4.1.2. The numeric types have a full set of corresponding arithmetic operators and functions. Refer to Chapter 9 for more information. The following sections describe the types in detail.

8.1.1. Integer Types

The types `smallint`, `integer`, and `bigint` store whole numbers, that is, numbers without fractional components, of various ranges. Attempts to store values outside of the allowed range will result in an error.

The type `integer` is the usual choice, as it offers the best balance between range, storage size, and performance. The `smallint` type is generally only used if disk space is at a premium. The `bigint` type should only be used if the `integer` range is not sufficient, because the latter is definitely faster.

The `bigint` type might not function correctly on all platforms, since it relies on compiler support for eight-byte integers. On a machine without such support, `bigint` acts the same as `integer` (but still takes up eight bytes of storage). However, we are not aware of any reasonable platform where this is actually the case.

SQL only specifies the integer types `integer` (or `int`), `smallint`, and `bigint`. The type names `int2`, `int4`, and `int8` are extensions, which are shared with various other SQL database systems.

8.1.2. Arbitrary Precision Numbers

The type `numeric` can store numbers with up to 1000 digits of precision and perform calculations exactly. It is especially recommended for storing monetary amounts and other quantities where exactness is required. However, arithmetic on `numeric` values is very slow compared to the integer types, or to the floating-point types described in the next section.

In what follows we use these terms: The `scale` of a `numeric` is the count of decimal digits in the fractional part, to the right of the decimal point. The `precision` of a `numeric` is the total count of significant digits in the whole number, that is, the number of digits to both sides of the decimal point. So the number 23.5141 has a precision of 6 and a scale of 4. Integers can be considered to have a scale of zero.

Both the maximum precision and the maximum scale of a `numeric` column can be configured. To declare a column of type `numeric` use the syntax:

---

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
<th>Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>decimal</td>
<td>variable</td>
<td>user-specified precision, exact</td>

</tr>
</tbody>
</table>
Chapter 8. Data Types

NUMERIC(\textit{precision, scale})

The precision must be positive, the scale zero or positive. Alternatively:

NUMERIC(\textit{precision})

selects a scale of 0. Specifying:

NUMERIC

without any precision or scale creates a column in which numeric values of any precision and scale can be stored, up to the implementation limit on precision. A column of this kind will not coerce input values to any particular scale, whereas numeric columns with a declared scale will coerce input values to that scale. (The SQL standard requires a default scale of 0, i.e., coercion to integer precision. We find this a bit useless. If you’re concerned about portability, always specify the precision and scale explicitly.)

If the scale of a value to be stored is greater than the declared scale of the column, the system will round the value to the specified number of fractional digits. Then, if the number of digits to the left of the decimal point exceeds the declared precision minus the declared scale, an error is raised.

Numeric values are physically stored without any extra leading or trailing zeroes. Thus, the declared precision and scale of a column are maximums, not fixed allocations. (In this sense the numeric type is more akin to \textit{varchar(\textit{n})} than to \textit{char(\textit{n})}.) The actual storage requirement is two bytes for each group of four decimal digits, plus five to eight bytes overhead.

In addition to ordinary numeric values, the \textit{numeric} type allows the special value NaN, meaning “not-a-number”. Any operation on NaN yields another NaN. When writing this value as a constant in a SQL command, you must put quotes around it, for example \texttt{UPDATE table SET x = ‘NaN’}. On input, the string \texttt{NaN} is recognized in a case-insensitive manner.

\textbf{Note:} In most implementations of the “not-a-number” concept, NaN is not considered equal to any other numeric value (including NaN). In order to allow numeric values to be sorted and used in tree-based indexes, PostgreSQL treats NaN values as equal, and greater than all non-NaN values.

The types \textit{decimal} and \textit{numeric} are equivalent. Both types are part of the SQL standard.

8.1.3. Floating-Point Types

The data types \textit{real} and \textit{double precision} are inexact, variable-precision numeric types. In practice, these types are usually implementations of IEEE Standard 754 for Binary Floating-Point Arithmetic (single and double precision, respectively), to the extent that the underlying processor, operating system, and compiler support it.

Inexact means that some values cannot be converted exactly to the internal format and are stored as approximations, so that storing and printing back out a value might show slight discrepancies. Managing these errors and how they propagate through calculations is the subject of an entire branch of mathematics and computer science and will not be discussed further here, except for the following points:

- If you require exact storage and calculations (such as for monetary amounts), use the \textit{numeric} type instead.
• If you want to do complicated calculations with these types for anything important, especially if you rely on certain behavior in boundary cases (infinity, underflow), you should evaluate the implementation carefully.

• Comparing two floating-point values for equality might or might not work as expected.

On most platforms, the `real` type has a range of at least 1E-37 to 1E+37 with a precision of at least 6 decimal digits. The `double precision` type typically has a range of around 1E-307 to 1E+308 with a precision of at least 15 digits. Values that are too large or too small will cause an error. Rounding might take place if the precision of an input number is too high. Numbers too close to zero that are not representable as distinct from zero will cause an underflow error.

In addition to ordinary numeric values, the floating-point types have several special values:

- `Infinity`
- `-Infinity`
- `NaN`

These represent the IEEE 754 special values “infinity”, “negative infinity”, and “not-a-number”, respectively. (On a machine whose floating-point arithmetic does not follow IEEE 754, these values will probably not work as expected.) When writing these values as constants in a SQL command, you must put quotes around them, for example `UPDATE table SET x = 'Infinity'`. On input, these strings are recognized in a case-insensitive manner.

**Note:** PostgreSQL treats `NaN` values as equal, and greater than all non-`NaN` values.

PostgreSQL also supports the SQL-standard notations `float` and `float(p)` for specifying inexact numeric types. Here, `p` specifies the minimum acceptable precision in binary digits. PostgreSQL accepts `float(1)` to `float(24)` as selecting the `real` type, while `float(25)` to `float(53)` select `double precision`. Values of `p` outside the allowed range draw an error. `float` with no precision specified is taken to mean `double precision`.

**Note:** Prior to PostgreSQL 7.4, the precision in `float(p)` was taken to mean so many decimal digits. This has been corrected to match the SQL standard, which specifies that the precision is measured in binary digits. The assumption that `real` and `double precision` have exactly 24 and 53 bits in the mantissa respectively is correct for IEEE-standard floating point implementations. On non-IEEE platforms it might be off a little, but for simplicity the same ranges of `p` are used on all platforms.

### 8.1.4. Serial Types

The data types `serial` and `bigserial` are not true types, but merely a notational convenience for setting up unique identifier columns (similar to the `AUTO_INCREMENT` property supported by some other databases). In the current implementation, specifying:

```sql
CREATE TABLE tablename (  
    colname SERIAL  
) ;
```
is equivalent to specifying:

```sql
CREATE SEQUENCE tablename_colname_seq;
CREATE TABLE tablename (  
    colname integer NOT NULL DEFAULT nextval('tablename_colname_seq')
);
ALTER SEQUENCE tablename_colname_seq OWNED BY tablename.colname;
```

Thus, we have created an integer column and arranged for its default values to be assigned from a sequence generator. A `NOT NULL` constraint is applied to ensure that a null value cannot be explicitly inserted, either. (In most cases you would also want to attach a `UNIQUE` or `PRIMARY KEY` constraint to prevent duplicate values from being inserted by accident, but this is not automatic.) Lastly, the sequence is marked as “owned by” the column, so that it will be dropped if the column or table is dropped.

**Note:** Prior to PostgreSQL 7.3, `serial` implied `UNIQUE`. This is no longer automatic. If you wish a serial column to be in a unique constraint or a primary key, it must now be specified, same as with any other data type.

To insert the next value of the sequence into the `serial` column, specify that the `serial` column should be assigned its default value. This can be done either by excluding the column from the list of columns in the `INSERT` statement, or through the use of the `DEFAULT` key word.

The type names `serial` and `serial4` are equivalent: both create integer columns. The type names `bigserial` and `serial8` work just the same way, except that they create a `bigint` column. `bigserial` should be used if you anticipate the use of more than $2^{31}$ identifiers over the lifetime of the table.

The sequence created for a `serial` column is automatically dropped when the owning column is dropped. You can drop the sequence without dropping the column, but this will force removal of the column default expression.

### 8.2. Monetary Types

The `money` type stores a currency amount with a fixed fractional precision; see Table 8-3. Input is accepted in a variety of formats, including integer and floating-point literals, as well as “typical” currency formatting, such as ‘$1,000.00’. Output is generally in the latter form but depends on the locale. Non-quoted numeric values can be converted to `money` by casting the numeric value to `text` and then `money`:

```sql
SELECT 1234::text::money;
```

There is no simple way of doing the reverse in a locale-independent manner, namely casting a `money` value to a numeric type. If you know the currency symbol and thousands separator you can use `regexp_replace()`:

```sql
SELECT regexp_replace('52093.89':money::text, '[$,]', ',', 'g')::numeric;
```
Since the output of this data type is locale-sensitive, it may not work to load `money` data into a database that has a different setting of `lc_monetary`. To avoid problems, before restoring a dump make sure `lc_monetary` has the same or equivalent value as in the database that was dumped.

**Table 8-3. Monetary Types**

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
<th>Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>money</td>
<td>8 bytes</td>
<td>currency amount</td>
<td>-92233720368547758.08 to +92233720368547758.07</td>
</tr>
</tbody>
</table>

**8.3. Character Types**

**Table 8-4. Character Types**

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>character varying((n)), varchar((n))</td>
<td>variable-length with limit</td>
</tr>
<tr>
<td>character((n)), char((n))</td>
<td>fixed-length, blank padded</td>
</tr>
<tr>
<td>text</td>
<td>variable unlimited length</td>
</tr>
</tbody>
</table>

Table 8-4 shows the general-purpose character types available in PostgreSQL.

SQL defines two primary character types: `character varying\((n)\)` and `character\((n)\)`, where \(n\) is a positive integer. Both of these types can store strings up to \(n\) characters in length. An attempt to store a longer string into a column of these types will result in an error, unless the excess characters are all spaces, in which case the string will be truncated to the maximum length. (This somewhat bizarre exception is required by the SQL standard.) If the string to be stored is shorter than the declared length, values of type `character` will be space-padded; values of type `character varying` will simply store the shorter string.

If one explicitly casts a value to `character varying\((n)\)` or `character\((n)\)`, then an over-length value will be truncated to \(n\) characters without raising an error. (This too is required by the SQL standard.)

The notations `varchar\((n)\)` and `char\((n)\)` are aliases for `character varying\((n)\)` and `character\((n)\)`, respectively. `character` without length specifier is equivalent to `character\(1\)`.

If `character varying` is used without length specifier, the type accepts strings of any size. The latter is a PostgreSQL extension.

In addition, PostgreSQL provides the `text` type, which stores strings of any length. Although the type `text` is not in the SQL standard, several other SQL database management systems have it as well.

Values of type `character` are physically padded with spaces to the specified width \(n\), and are stored and displayed that way. However, the padding spaces are treated as semantically insignificant. Trailing spaces are disregarded when comparing two values of type `character`, and they will be removed when converting a `character` value to one of the other string types. Note that trailing spaces are not semantically significant in `character varying` and `text` values.

The storage requirement for a short string (up to 126 bytes) is 1 byte plus the actual string, which
includes the space padding in the case of character. Longer strings have 4 bytes overhead instead of 1. Long strings are compressed by the system automatically, so the physical requirement on disk might be less. Very long values are also stored in background tables so that they do not interfere with rapid access to shorter column values. In any case, the longest possible character string that can be stored is about 1 GB. (The maximum value that will be allowed for \( n \) in the data type declaration is less than that. It wouldn’t be very useful to change this because with multibyte character encodings the number of characters and bytes can be quite different anyway. If you desire to store long strings with no specific upper limit, use text or character varying without a length specifier, rather than making up an arbitrary length limit.)

**Tip:** There are no performance differences between these three types, apart from increased storage size when using the blank-padded type, and a few extra cycles to check the length when storing into a length-constrained column. While character\((n)\) has performance advantages in some other database systems, it has no such advantages in PostgreSQL. In most situations text or character varying should be used instead.

Refer to Section 4.1.2.1 for information about the syntax of string literals, and to Chapter 9 for information about available operators and functions. The database character set determines the character set used to store textual values; for more information on character set support, refer to Section 22.2.

**Example 8-1. Using the character types**

```
CREATE TABLE test1 (a character(4));
INSERT INTO test1 VALUES ('ok');
SELECT a, char_length(a) FROM test1; -- 1
   a | char_length
 ----+-------------
   ok | 2

CREATE TABLE test2 (b varchar(5));
INSERT INTO test2 VALUES ('ok');
INSERT INTO test2 VALUES ('good');
INSERT INTO test2 VALUES ('too long');
ERROR: value too long for type character varying(5)
INSERT INTO test2 VALUES ('too long':varchar(5)); -- explicit truncation
SELECT b, char_length(b) FROM test2;
   b | char_length
 ----+-------------
   ok | 2
   good | 5
   too | 5

1 The `char_length` function is discussed in Section 9.4.
```

There are two other fixed-length character types in PostgreSQL, shown in Table 8-5. The name type exists only for storage of identifiers in the internal system catalogs and is not intended for use by the general user. Its length is currently defined as 64 bytes (63 usable characters plus terminator) but should be referenced using the constant NAMEDATALEN. The length is set at compile time (and is therefore adjustable for special uses); the default maximum length might change in a future release. The type "char" (note the quotes) is different from char\((1)\) in that it only uses one byte of storage. It is internally used in the system catalogs as a poor-man’s enumeration type.
8.4. Binary Data Types

The `bytea` data type allows storage of binary strings; see Table 8-6.

Table 8-6. Binary Data Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>bytea</td>
<td>1 or 4 bytes plus the actual binary string</td>
<td>variable-length binary string</td>
</tr>
</tbody>
</table>

A binary string is a sequence of octets (or bytes). Binary strings are distinguished from character strings by two characteristics: First, binary strings specifically allow storing octets of value zero and other “non-printable” octets (usually, octets outside the range 32 to 126). Character strings disallow zero octets, and also disallow any other octet values and sequences of octet values that are invalid according to the database’s selected character set encoding. Second, operations on binary strings process the actual bytes, whereas the processing of character strings depends on locale settings. In short, binary strings are appropriate for storing data that the programmer thinks of as “raw bytes”, whereas character strings are appropriate for storing text.

When entering `bytea` values, octets of certain values must be escaped (but all octet values can be escaped) when used as part of a string literal in an SQL statement. In general, to escape an octet, it is converted into the three-digit octal number equivalent of its decimal octet value, and preceded by two backslashes. Table 8-7 shows the characters that must be escaped, and gives the alternative escape sequences where applicable.

Table 8-7. `bytea` Literal Escaped Octets

<table>
<thead>
<tr>
<th>Decimal Octet Value</th>
<th>Description</th>
<th>Escaped Input Representation</th>
<th>Example</th>
<th>Output Representation</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>zero octet</td>
<td><code>E'\000'</code></td>
<td><code>SELECT E'\000':bytea;</code></td>
<td>\000</td>
</tr>
<tr>
<td>39</td>
<td>single quote</td>
<td><code>&quot; or E'\047'</code></td>
<td><code>SELECT E&quot;':bytea;</code></td>
<td>'</td>
</tr>
<tr>
<td>92</td>
<td>backslash</td>
<td><code>E''\134'</code> or <code>E'\134'</code></td>
<td><code>SELECT E''':bytea</code></td>
<td>\</td>
</tr>
<tr>
<td>0 to 31 and 127 to 255</td>
<td>“non-printable” octets</td>
<td><code>E'\xxx'</code> (octal value)</td>
<td><code>SELECT E'\001':bytea;</code></td>
<td>\001</td>
</tr>
</tbody>
</table>

The requirement to escape “non-printable” octets actually varies depending on locale settings. In some
instances you can get away with leaving them unescaped. Note that the result in each of the examples in Table 8-7 was exactly one octet in length, even though the output representation of the zero octet and backslash are more than one character.

The reason that you have to write so many backslashes, as shown in Table 8-7, is that an input string written as a string literal must pass through two parse phases in the PostgreSQL server. The first backslash of each pair is interpreted as an escape character by the string-literal parser (assuming escape string syntax is used) and is therefore consumed, leaving the second backslash of the pair. (Dollar-quoted strings can be used to avoid this level of escaping.) The remaining backslash is then recognized by the bytea input function as starting either a three digit octal value or escaping another backslash. For example, a string literal passed to the server as E'\001' becomes \001 after passing through the escape string parser. The \001 is then sent to the bytea input function, where it is converted to a single octet with a decimal value of 1. Note that the single-quote character is not treated specially by bytea, so it follows the normal rules for string literals. (See also Section 4.1.2.1.) Bytea octets are also escaped in the output. In general, each “non-printable” octet is converted into its equivalent three-digit octal value and preceded by one backslash. Most “printable” octets are represented by their standard representation in the client character set. The octet with decimal value 92 (backslash) has a special alternative output representation. Details are in Table 8-8.

Table 8-8. bytea Output Escaped Octets

<table>
<thead>
<tr>
<th>Decimal Octet Value</th>
<th>Description</th>
<th>Escaped Output Representation</th>
<th>Example</th>
<th>Output Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>92</td>
<td>backslash</td>
<td>\ \</td>
<td>SELECT E'\134'::bytea;</td>
<td>\ \</td>
</tr>
<tr>
<td>0 to 31 and 127 to 255</td>
<td>“non-printable” octets</td>
<td>\xxx (octal value)</td>
<td>SELECT E'\001'::bytea;</td>
<td>\001</td>
</tr>
<tr>
<td>32 to 126</td>
<td>“printable” octets</td>
<td>client character set representation</td>
<td>SELECT E'\176'::bytea;</td>
<td>~</td>
</tr>
</tbody>
</table>

Depending on the front end to PostgreSQL you use, you might have additional work to do in terms of escaping and unescaping bytea strings. For example, you might also have to escape line feeds and carriage returns if your interface automatically translates these.

The SQL standard defines a different binary string type, called BLOB or BINARY LARGE OBJECT. The input format is different from bytea, but the provided functions and operators are mostly the same.

8.5. Date/Time Types

PostgreSQL supports the full set of SQL date and time types, shown in Table 8-9. The operations available on these data types are described in Section 9.9.

Table 8-9. Date/Time Types
<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
<th>Low Value</th>
<th>High Value</th>
<th>Resolution</th>
</tr>
</thead>
<tbody>
<tr>
<td>timestamp [(p)] [without time zone]</td>
<td>8 bytes</td>
<td>both date and time</td>
<td>4713 BC</td>
<td>5874897 AD</td>
<td>1 microsecond / 14 digits</td>
</tr>
<tr>
<td>timestamp [(p)] [with time zone]</td>
<td>8 bytes</td>
<td>both date and time, with time zone</td>
<td>4713 BC</td>
<td>5874897 AD</td>
<td>1 microsecond / 14 digits</td>
</tr>
<tr>
<td>interval [(p)]</td>
<td>12 bytes</td>
<td>time intervals</td>
<td>-178000000 years</td>
<td>178000000 years</td>
<td>1 microsecond / 14 digits</td>
</tr>
<tr>
<td>date</td>
<td>4 bytes</td>
<td>dates only</td>
<td>4713 BC</td>
<td>5874897 AD</td>
<td>1 day</td>
</tr>
<tr>
<td>time [(p)] [without time zone]</td>
<td>8 bytes</td>
<td>times of day only</td>
<td>00:00:00</td>
<td>24:00:00</td>
<td>1 microsecond / 14 digits</td>
</tr>
<tr>
<td>time [(p)] [with time zone]</td>
<td>12 bytes</td>
<td>times of day only, with time zone</td>
<td>00:00:00+1459</td>
<td>24:00:00-1459</td>
<td>1 microsecond / 14 digits</td>
</tr>
</tbody>
</table>

**Note:** Prior to PostgreSQL 7.3, writing just timestamp was equivalent to timestamp with time zone. This was changed for SQL compliance.

time, timestamp, and interval accept an optional precision value p which specifies the number of fractional digits retained in the seconds field. By default, there is no explicit bound on precision. The allowed range of p is from 0 to 6 for the timestamp and interval types.

**Note:** When timestamp values are stored as double precision floating-point numbers (currently the default), the effective limit of precision might be less than 6. Timestamp values are stored as seconds before or after midnight 2000-01-01. Microsecond precision is achieved for dates within a few years of 2000-01-01, but the precision degrades for dates further away. When timestamp values are stored as eight-byte integers (a compile-time option), microsecond precision is available over the full range of values. However eight-byte integer timestamps have a more limited range of dates than shown above: from 4713 BC up to 294276 AD. The same compile-time option also determines whether time and interval values are stored as floating-point or eight-byte integers. In the floating-point case, large interval values degrade in precision as the size of the interval increases.

For the time types, the allowed range of p is from 0 to 6 when eight-byte integer storage is used, or from 0 to 10 when floating-point storage is used.

The type time with time zone is defined by the SQL standard, but the definition exhibits properties which lead to questionable usefulness. In most cases, a combination of date, time, timestamp without time zone, and timestamp with time zone should provide a complete range of date/time functionality required by any application.

The types abstime and reltime are lower precision types which are used internally. You are discouraged from using these types in new applications and are encouraged to move any old ones over when appropriate. Any or all of these internal types might disappear in a future release.
8.5.1. Date/Time Input

Date and time input is accepted in almost any reasonable format, including ISO 8601, SQL-compatible, traditional POSTGRES, and others. For some formats, ordering of month, day, and year in date input is ambiguous and there is support for specifying the expected ordering of these fields. Set the DateStyle parameter to MDY to select month-day-year interpretation, DMY to select day-month-year interpretation, or YMD to select year-month-day interpretation.

PostgreSQL is more flexible in handling date/time input than the SQL standard requires. See Appendix B for the exact parsing rules of date/time input and for the recognized text fields including months, days of the week, and time zones.

Remember that any date or time literal input needs to be enclosed in single quotes, like text strings. Refer to Section 4.1.2.5 for more information. SQL requires the following syntax

type [ (p) ] 'value'

where \( p \) in the optional precision specification is an integer corresponding to the number of fractional digits in the seconds field. Precision can be specified for time, timestamp, and interval types. The allowed values are mentioned above. If no precision is specified in a constant specification, it defaults to the precision of the literal value.

8.5.1.1. Dates

Table 8-10 shows some possible inputs for the date type.

Table 8-10. Date Input

<table>
<thead>
<tr>
<th>Example</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>January 8, 1999</td>
<td>unambiguous in any datestyle input mode</td>
</tr>
<tr>
<td>1999-01-08</td>
<td>ISO 8601; January 8 in any mode (recommended format)</td>
</tr>
<tr>
<td>1/8/1999</td>
<td>January 8 in MDY mode; August 1 in DMY mode</td>
</tr>
<tr>
<td>1/18/1999</td>
<td>January 18 in MDY mode; rejected in other modes</td>
</tr>
<tr>
<td>01/02/03</td>
<td>January 2, 2003 in MDY mode; February 1, 2003 in DMY mode; February 3, 2001 in YMD mode</td>
</tr>
<tr>
<td>1999-Jan-08</td>
<td>January 8 in any mode</td>
</tr>
<tr>
<td>Jan-08-1999</td>
<td>January 8 in any mode</td>
</tr>
<tr>
<td>08-Jan-1999</td>
<td>January 8 in any mode</td>
</tr>
<tr>
<td>99-Jan-08</td>
<td>January 8 in YMD mode, else error</td>
</tr>
<tr>
<td>08-Jan-99</td>
<td>January 8, except error in YMD mode</td>
</tr>
<tr>
<td>Jan-08-99</td>
<td>January 8, except error in YMD mode</td>
</tr>
<tr>
<td>19990108</td>
<td>ISO 8601; January 8, 1999 in any mode</td>
</tr>
<tr>
<td>990108</td>
<td>ISO 8601; January 8, 1999 in any mode</td>
</tr>
<tr>
<td>1999.008</td>
<td>year and day of year</td>
</tr>
<tr>
<td>12451187</td>
<td>Julian day</td>
</tr>
<tr>
<td>January 8, 99 BC</td>
<td>year 99 before the Common Era</td>
</tr>
</tbody>
</table>
8.5.1.2. Times

The time-of-day types are time [ (p) ] without time zone and time [ (p) ] with time zone. Writing just time is equivalent to time without time zone.

Valid input for these types consists of a time of day followed by an optional time zone. (See Table 8-11 and Table 8-12.) If a time zone is specified in the input for time without time zone, it is silently ignored. You can also specify a date but it will be ignored, except when you use a time zone name that involves a daylight-savings rule, such as America/New_York. In this case specifying the date is required in order to determine whether standard or daylight-savings time applies. The appropriate time zone offset is recorded in the time with time zone value.

Table 8-11. Time Input

<table>
<thead>
<tr>
<th>Example</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>04:05:06.789</td>
<td>ISO 8601</td>

<td>ISO-8601 offset for PST</td>
</tr>
<tr>
<td>zulu</td>
<td>Military abbreviation for UTC</td>
</tr>
<tr>
<td>z</td>
<td>Short form of zulu</td>
</tr>
</tbody>
</table>

Refer to Section 8.5.3 for more information on how to specify time zones.

8.5.1.3. Time Stamps

Valid input for the time stamp types consists of a concatenation of a date and a time, followed by an optional time zone, followed by an optional AD or BC. (Alternatively, AD/BC can appear before the
time zone, but this is not the preferred ordering.) Thus:

1999-01-08 04:05:06

and:

1999-01-08 04:05:06 -8:00

are valid values, which follow the ISO 8601 standard. In addition, the wide-spread format:

January 8 04:05:06 1999 PST

is supported.

The SQL standard differentiates \texttt{timestamp without time zone} and \texttt{timestamp with time zone} literals by the presence of a “+” or “-”. Hence, according to the standard,

\texttt{TIMESTAMP '2004-10-19 10:23:54'}

is a \texttt{timestamp without time zone}, while

\texttt{TIMESTAMP '2004-10-19 10:23:54+02'}

is a \texttt{timestamp with time zone}. PostgreSQL never examines the content of a literal string before determining its type, and therefore will treat both of the above as \texttt{timestamp without time zone}. To ensure that a literal is treated as \texttt{timestamp with time zone}, give it the correct explicit type:

\texttt{TIMESTAMP WITH TIME ZONE '2004-10-19 10:23:54+02'}

In a literal that has been decided to be \texttt{timestamp without time zone}, PostgreSQL will silently ignore any time zone indication. That is, the resulting value is derived from the date/time fields in the input value, and is not adjusted for time zone.

For \texttt{timestamp with time zone}, the internally stored value is always in UTC (Universal Coordinated Time, traditionally known as Greenwich Mean Time, GMT). An input value that has an explicit time zone specified is converted to UTC using the appropriate offset for that time zone. If no time zone is stated in the input string, then it is assumed to be in the time zone indicated by the system’s timezone parameter, and is converted to UTC using the offset for the timezone zone.

When a \texttt{timestamp with time zone} value is output, it is always converted from UTC to the current timezone zone, and displayed as local time in that zone. To see the time in another time zone, either change timezone or use the AT TIME ZONE construct (see Section 9.9.3).

Conversions between \texttt{timestamp without time zone} and \texttt{timestamp with time zone} normally assume that the \texttt{timestamp without time zone} value should be taken or given as timezone local time. A different zone reference can be specified for the conversion using AT TIME ZONE.

\subsection{8.5.1.4. Intervals}

\texttt{interval} values can be written with the following syntax:

\texttt{[@] quantity unit [quantity unit...] [direction]}

Where: \texttt{quantity} is a number (possibly signed); \texttt{unit} is \texttt{microsecond}, \texttt{millisecond}, \texttt{second}, \texttt{minute}, \texttt{hour}, \texttt{day}, \texttt{week}, \texttt{month}, \texttt{year}, \texttt{decade}, \texttt{century}, \texttt{millennium}, or abbreviations or plu-
Chapter 8. Data Types

...ernals of these units; direction can be ago or empty. The at sign (@) is optional noise. The amounts of different units are implicitly added up with appropriate sign accounting.

Quantities of days, hours, minutes, and seconds can be specified without explicit unit markings. For example, ‘1 12:59:10’ is read the same as ‘1 day 12 hours 59 min 10 sec’.

The optional subsecond precision $p$ should be between 0 and 6, and defaults to the precision of the input literal.

Internally interval values are stored as months, days, and seconds. This is done because the number of days in a month varies, and a day can have 23 or 25 hours if a daylight savings time adjustment is involved. Because intervals are usually created from constant strings or timestamp subtraction, this storage method works well in most cases. Functions justify_days and justify_hours are available for adjusting days and hours that overflow their normal periods.

8.5.1.5. Special Values

PostgreSQL supports several special date/time input values for convenience, as shown in Table 8-13. The values infinity and -infinity are specially represented inside the system and will be displayed the same way; but the others are simply notational shorthands that will be converted to ordinary date/time values when read. (In particular, now and related strings are converted to a specific time value as soon as they are read.) All of these values need to be written in single quotes when used as constants in SQL commands.

Table 8-13. Special Date/Time Inputs

<table>
<thead>
<tr>
<th>Input String</th>
<th>Valid Types</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>epoch</td>
<td>date, timestamp</td>
<td>1970-01-01 00:00:00+00 (Unix system time zero)</td>
</tr>
<tr>
<td>infinity</td>
<td>timestamp</td>
<td>later than all other time stamps</td>
</tr>
<tr>
<td>-infinity</td>
<td>timestamp</td>
<td>earlier than all other time stamps</td>
</tr>
<tr>
<td>now</td>
<td>date, time, timestamp</td>
<td>current transaction’s start time</td>
</tr>
<tr>
<td>today</td>
<td>date, timestamp</td>
<td>midnight today</td>
</tr>
<tr>
<td>tomorrow</td>
<td>date, timestamp</td>
<td>midnight tomorrow</td>
</tr>
<tr>
<td>yesterday</td>
<td>date, timestamp</td>
<td>midnight yesterday</td>
</tr>
<tr>
<td>allballs</td>
<td>time</td>
<td>00:00:00.00 UTC</td>
</tr>
</tbody>
</table>

The following SQL-compatible functions can also be used to obtain the current time value for the corresponding data type: CURRENT_DATE, CURRENT_TIME, CURRENT_TIMESTAMP, LOCALTIME, LOCALTIMESTAMP. The latter four accept an optional subsecond precision specification. (See Section 9.9.4.) Note however that these are SQL functions and are not recognized as data input strings.

8.5.2. Date/Time Output

The output format of the date/time types can be set to one of the four styles ISO 8601, SQL (Ingres), traditional POSTGRES, and German, using the command SET datestyle. The default is the ISO format. (The SQL standard requires the use of the ISO 8601 format. The name of the “SQL” output format is a historical accident.) Table 8-14 shows examples of each output style. The output of the date and time types is of course only the date or time part in accordance with the given examples.
Table 8-14. Date/Time Output Styles

<table>
<thead>
<tr>
<th>Style Specification</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>ISO</td>
<td>ISO 8601/SQL standard</td>
<td>1997-12-17 07:37:16-08</td>
</tr>
<tr>
<td>SQL</td>
<td>traditional style</td>
<td>12/17/1997 07:37:16.00 PST</td>
</tr>
<tr>
<td>POSTGRES</td>
<td>original style</td>
<td>Wed Dec 17 07:37:16 1997 PST</td>
</tr>
<tr>
<td>German</td>
<td>regional style</td>
<td>17.12.1997 07:37:16.00 PST</td>
</tr>
</tbody>
</table>

In the SQL and POSTGRES styles, day appears before month if DMY field ordering has been specified, otherwise month appears before day. (See Section 8.5.1 for how this setting also affects interpretation of input values.) Table 8-15 shows an example.

Table 8-15. Date Order Conventions

<table>
<thead>
<tr>
<th>datestyle Setting</th>
<th>Input Ordering</th>
<th>Example Output</th>
</tr>
</thead>
<tbody>
<tr>
<td>SQL, DMY</td>
<td>day/month/year</td>
<td>17/12/1997 15:37:16.00 CET</td>
</tr>
<tr>
<td>SQL, MDY</td>
<td>month/day/year</td>
<td>12/17/1997 07:37:16.00 PST</td>
</tr>
<tr>
<td>Postgres, DMY</td>
<td>day/month/year</td>
<td>Wed 17 Dec 07:37:16 1997 PST</td>
</tr>
</tbody>
</table>

interval output looks like the input format, except that units like century or week are converted to years and days and ago is converted to an appropriate sign. In ISO mode the output looks like:

```
[ quantity unit [ ... ] ] [ days ] [ hours:minutes:seconds ]
```

The date/time styles can be selected by the user using the SET datestyle command, the DateStyle parameter in the postgresql.conf configuration file, or the PGDATETIME environment variable on the server or client. The formatting function to_char (see Section 9.8) is also available as a more flexible way to format the date/time output.

### 8.5.3. Time Zones

Time zones, and time-zone conventions, are influenced by political decisions, not just earth geometry. Time zones around the world became somewhat standardized during the 1900’s, but continue to be prone to arbitrary changes, particularly with respect to daylight-savings rules. PostgreSQL currently supports daylight-savings rules over the time period 1902 through 2038 (corresponding to the full range of conventional Unix system time). Times outside that range are taken to be in “standard time” for the selected time zone, no matter what part of the year they fall in.

PostgreSQL endeavors to be compatible with the SQL standard definitions for typical usage. However, the SQL standard has an odd mix of date and time types and capabilities. Two obvious problems are:

- Although the date type does not have an associated time zone, the time type can. Time zones in the real world have little meaning unless associated with a date as well as a time, since the offset can vary through the year with daylight-saving time boundaries.
- The default time zone is specified as a constant numeric offset from UTC. It is therefore not possible to adapt to daylight-saving time when doing date/time arithmetic across DST boundaries.
To address these difficulties, we recommend using date/time types that contain both date and time when using time zones. We recommend not using the type time with time zone (though it is supported by PostgreSQL for legacy applications and for compliance with the SQL standard). PostgreSQL assumes your local time zone for any type containing only date or time.

All timezone-aware dates and times are stored internally in UTC. They are converted to local time in the zone specified by the timezone configuration parameter before being displayed to the client.

PostgreSQL allows you to specify time zones in three different forms:

- A full time zone name, for example America/New_York. The recognized time zone names are listed in the pg_timezone_names view (see Section 44.56). PostgreSQL uses the widely-used zic time zone data for this purpose, so the same names are also recognized by much other software.

- A time zone abbreviation, for example PST. Such a specification merely defines a particular offset from UTC, in contrast to full time zone names which might imply a set of daylight savings transition-date rules as well. The recognized abbreviations are listed in the pg_timezone_abbrevs view (see Section 44.55). You cannot set the configuration parameters timezone or log_timezone using a time zone abbreviation, but you can use abbreviations in date/time input values and with the AT TIME ZONE operator.

- In addition to the timezone names and abbreviations, PostgreSQL will accept POSIX-style time zone specifications of the form STDoffset or STDoffsetDST, where STD is a zone abbreviation, offset is a numeric offset in hours west from UTC, and DST is an optional daylight-savings zone abbreviation, assumed to stand for one hour ahead of the given offset. For example, if EST5EDT were not already a recognized zone name, it would be accepted and would be functionally equivalent to USA East Coast time. When a daylight-savings zone name is present, it is assumed to be used according to the same daylight-savings transition rules used in the zic time zone database’s posixrules entry. In a standard PostgreSQL installation, posixrules is the same as US/Eastern, so that POSIX-style time zone specifications follow USA daylight-savings rules. If needed, you can adjust this behavior by replacing the posixrules file.

There is a conceptual and practical difference between the abbreviations and the full names: abbreviations always represent a fixed offset from UTC, whereas most of the full names imply a local daylight-savings time rule and so have two possible UTC offsets.

One should be wary that the POSIX-style time zone feature can lead to silently accepting bogus input, since there is no check on the reasonableness of the zone abbreviations. For example, SET TIMEZONE TO FOOBAR0 will work, leaving the system effectively using a rather peculiar abbreviation for UTC.

Another issue to keep in mind is that in POSIX time zone names, positive offsets are used for locations west of Greenwich. Everywhere else, PostgreSQL follows the ISO-8601 convention that positive timezone offsets are east of Greenwich.

In all cases, timezone names are recognized case-insensitively. (This is a change from PostgreSQL versions prior to 8.2, which were case-sensitive in some contexts and not others.)

Neither full names nor abbreviations are hard-wired into the server; they are obtained from configuration files stored under .../share/timezone/ and .../share/timezonesets/ of the installation directory (see Section B.3).

The timezone configuration parameter can be set in the file postgresql.conf, or in any of the other standard ways described in Chapter 18. There are also several special ways to set it:

- If timezone is not specified in postgresql.conf nor as a server command-line option, the server attempts to use the value of the TZ environment variable as the default time zone. If TZ is
Chapter 8. Data Types

not defined or is not any of the time zone names known to PostgreSQL, the server attempts to
determine the operating system’s default time zone by checking the behavior of the C library func-
tion \texttt{localtime()}. The default time zone is selected as the closest match among PostgreSQL’s
known time zones. (These rules are also used to choose the default value of \texttt{log\_timezone}, if it is
not specified.)

• The SQL command \texttt{SET TIME ZONE} sets the time zone for the session. This is an alternative
   spelling of \texttt{SET TIMEZONE TO} with a more SQL-spec-compatible syntax.

• The \texttt{PGTZ} environment variable, if set at the client, is used by libpq applications to send a \texttt{SET
   TIME ZONE} command to the server upon connection.

8.5.4. Internals

PostgreSQL uses Julian dates for all date/time calculations. They have the nice property of correctly
predicting/calculating any date more recent than 4713 BC to far into the future, using the assumption
that the length of the year is 365.2425 days.

Date conventions before the 19th century make for interesting reading, but are not consistent enough
to warrant coding into a date/time handler.

8.6. Boolean Type

PostgreSQL provides the standard SQL type \texttt{boolean}. \texttt{boolean} can have one of only two states:
“true” or “false”. A third state, “unknown”, is represented by the SQL null value.

Valid literal values for the “true” state are:

\begin{verbatim}
TRUE
    't'
    'true'
    'y'
    'yes'
    '1'
\end{verbatim}

For the “false” state, the following values can be used:

\begin{verbatim}
FALSE
    'f'
    'false'
    'n'
    'no'
    '0'
\end{verbatim}

Leading and trailing whitespace is ignored. Using the key words \texttt{TRUE} and \texttt{FALSE} is preferred (and
SQL-compliant).
Example 8-2. Using the boolean type

CREATE TABLE test1 (a boolean, b text);
INSERT INTO test1 VALUES (TRUE, 'sic est');
INSERT INTO test1 VALUES (FALSE, 'non est');
SELECT * FROM test1;

| a | b       |
|---+---------|
| t | sic est |
| f | non est |

SELECT * FROM test1 WHERE a;

| a | b       |
|---+---------|
| t | sic est |

Example 8-2 shows that boolean values are output using the letters t and f.

boolean uses 1 byte of storage.

8.7. Enumerated Types

Enumerated (enum) types are data types that are comprised of a static, predefined set of values with a specific order. They are equivalent to the enum types in a number of programming languages. An example of an enum type might be the days of the week, or a set of status values for a piece of data.

8.7.1. Declaration of Enumerated Types

Enum types are created using the CREATE TYPE command, for example:

CREATE TYPE mood AS ENUM ('sad', 'ok', 'happy');

Once created, the enum type can be used in table and function definitions much like any other type:

Example 8-3. Basic Enum Usage

CREATE TYPE mood AS ENUM ('sad', 'ok', 'happy');
CREATE TABLE person {
  name text,
  current_mood mood
};
INSERT INTO person VALUES ('Moe', 'happy');
SELECT * FROM person WHERE current_mood = 'happy';

<table>
<thead>
<tr>
<th>name</th>
<th>current_mood</th>
</tr>
</thead>
<tbody>
<tr>
<td>Moe</td>
<td>happy</td>
</tr>
</tbody>
</table>

(1 row)
8.7.2. Ordering

The ordering of the values in an enum type is the order in which the values were listed when the type was declared. All standard comparison operators and related aggregate functions are supported for enums. For example:

Example 8-4. Enum Ordering

```
INSERT INTO person VALUES ('Larry', 'sad');
INSERT INTO person VALUES ('Curly', 'ok');
SELECT * FROM person WHERE current_mood > 'sad';
  name | current_mood
--------+------------
  Moe   | happy
  Curly | ok
(2 rows)

SELECT * FROM person WHERE current_mood > 'sad' ORDER BY current_mood;
  name | current_mood
--------+------------
  Curly | ok
  Moe   | happy
(2 rows)

SELECT name FROM person
  WHERE current_mood = (SELECT MIN(current_mood) FROM person);
  name
--------
  Larry
(1 row)
```

8.7.3. Type Safety

Enumerated types are completely separate data types and may not be compared with each other.

Example 8-5. Lack of Casting

```
CREATE TYPE happiness AS ENUM ('happy', 'very happy', 'ecstatic');
CREATE TABLE holidays (
  num_weeks int,
  happiness happiness
);
INSERT INTO holidays(num_weeks,happiness) VALUES (4, 'happy');
INSERT INTO holidays(num_weeks,happiness) VALUES (6, 'very happy');
INSERT INTO holidays(num_weeks,happiness) VALUES (8, 'ecstatic');
INSERT INTO holidays(num_weeks,happiness) VALUES (2, 'sad');
ERROR: invalid input value for enum happiness: "sad"
SELECT person.name, holidays.num_weeks FROM person, holidays
  WHERE person.current_mood = holidays.happiness;
ERROR: operator does not exist: mood = happiness
```

If you really need to do something like that, you can either write a custom operator or add explicit casts to your query:
Chapter 8. Data Types

Example 8-6. Comparing Different Enums by Casting to Text

```sql
SELECT person.name, holidays.num_weeks FROM person, holidays
WHERE person.current_mood::text = holidays.happiness::text;
```

<table>
<thead>
<tr>
<th>name</th>
<th>num_weeks</th>
</tr>
</thead>
<tbody>
<tr>
<td>Moe</td>
<td>4</td>
</tr>
</tbody>
</table>

(1 row)

8.7.4. Implementation Details

An enum value occupies four bytes on disk. The length of an enum value’s textual label is limited by the NAMEDATALEN setting compiled into PostgreSQL; in standard builds this means at most 63 bytes.

Enum labels are case sensitive, so ‘happy’ is not the same as ‘HAPPY’. Spaces in the labels are significant, too.

8.8. Geometric Types

Geometric data types represent two-dimensional spatial objects. Table 8-16 shows the geometric types available in PostgreSQL. The most fundamental type, the point, forms the basis for all of the other types.

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Representation</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>point</td>
<td>16 bytes</td>
<td>Point on the plane</td>
<td>(x,y)</td>
</tr>
<tr>
<td>line</td>
<td>32 bytes</td>
<td>Infinite line (not fully implemented)</td>
<td>((x1,y1),(x2,y2))</td>
</tr>
<tr>
<td>lseg</td>
<td>32 bytes</td>
<td>Finite line segment</td>
<td>((x1,y1),(x2,y2))</td>
</tr>
<tr>
<td>box</td>
<td>32 bytes</td>
<td>Rectangular box</td>
<td>((x1,y1),(x2,y2))</td>
</tr>
<tr>
<td>path</td>
<td>16+16n bytes</td>
<td>Closed path (similar to polygon)</td>
<td>((x1,y1),...)</td>
</tr>
<tr>
<td>path</td>
<td>16+16n bytes</td>
<td>Open path</td>
<td>[(x1,y1),...</td>
</tr>
<tr>
<td>polygon</td>
<td>40+16n bytes</td>
<td>Polygon (similar to closed path)</td>
<td>((x1,y1),...)</td>
</tr>
<tr>
<td>circle</td>
<td>24 bytes</td>
<td>Circle</td>
<td>&lt;(x,y),r&gt; (center and radius)</td>
</tr>
</tbody>
</table>

A rich set of functions and operators is available to perform various geometric operations such as scaling, translation, rotation, and determining intersections. They are explained in Section 9.11.

8.8.1. Points

Points are the fundamental two-dimensional building block for geometric types. Values of type point are specified using either of the following syntaxes:

( x , y )
where \( x \) and \( y \) are the respective coordinates as floating-point numbers.

Points are output using the first syntax.

### 8.8.2. Line Segments

Line segments (lseg) are represented by pairs of points. Values of type `lseg` are specified using any of the following syntaxes:

\[
\begin{align*}
&[ ( x_1, \ y_1 ), \ ( x_2, \ y_2 ) ] \\
&( ( x_1, \ y_1 ), \ ( x_2, \ y_2 ) ) \\
&( x_1, \ y_1, \ x_2, \ y_2 )
\end{align*}
\]

where \( (x_1,y_1) \) and \( (x_2,y_2) \) are the end points of the line segment.

Line segments are output using the first syntax.

### 8.8.3. Boxes

Boxes are represented by pairs of points that are opposite corners of the box. Values of type `box` are specified using any of the following syntaxes:

\[
\begin{align*}
&( ( x_1, \ y_1 ), \ ( x_2, \ y_2 ) ) \\
&( x_1, \ y_1, \ x_2, \ y_2 )
\end{align*}
\]

where \( (x_1,y_1) \) and \( (x_2,y_2) \) are any two opposite corners of the box.

Boxes are output using the second syntax.

Any two opposite corners can be supplied on input, but the values will be reordered as needed to store the upper right and lower left corners, in that order.

### 8.8.4. Paths

Paths are represented by lists of connected points. Paths can be open, where the first and last points in the list are not considered connected, or closed, where the first and last points are considered connected.

Values of type `path` are specified using any of the following syntaxes:

\[
\begin{align*}
&[ ( x_1, \ y_1 ), \ ... , \ ( x_n, \ y_n ) ] \\
&( ( x_1, \ y_1 ), \ ... , \ ( x_n, \ y_n ) ) \\
&( x_1, \ y_1, \ ... , \ x_n, \ y_n )
\end{align*}
\]

where the points are the end points of the line segments comprising the path. Square brackets ([ ]) indicate an open path, while parentheses (()) indicate a closed path. When the outermost parentheses are omitted, as in the third through fifth syntaxes, a closed path is assumed.

Paths are output using the first syntax.
8.8.5. Polygons

Polygons are represented by lists of points (the vertexes of the polygon). Polygons should probably be considered equivalent to closed paths, but are stored differently and have their own set of support routines.

Values of type `polygon` are specified using any of the following syntaxes:

\[
( (x_1, y_1), \ldots, (x_n, y_n) )
\]

where the points are the end points of the line segments comprising the boundary of the polygon.

Polygons are output using the first syntax.

8.8.6. Circles

Circles are represented by a center point and a radius. Values of type `circle` are specified using any of the following syntaxes:

\[
\langle (x, y), r \rangle
\]

where \((x, y)\) is the center and \(r\) is the radius of the circle.

Circles are output using the first syntax.

8.9. Network Address Types

PostgreSQL offers data types to store IPv4, IPv6, and MAC addresses, as shown in Table 8-17. It is preferable to use these types instead of plain text types to store network addresses, because these types offer input error checking and several specialized operators and functions (see Section 9.12).

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>cidr</td>
<td>7 or 19 bytes</td>
<td>IPv4 and IPv6 networks</td>
</tr>
<tr>
<td>inet</td>
<td>7 or 19 bytes</td>
<td>IPv4 and IPv6 hosts and networks</td>
</tr>
<tr>
<td>macaddr</td>
<td>6 bytes</td>
<td>MAC addresses</td>
</tr>
</tbody>
</table>

When sorting `inet` or `cidr` data types, IPv4 addresses will always sort before IPv6 addresses, including IPv4 addresses encapsulated or mapped into IPv6 addresses, such as ::10.2.3.4 or ::ffff:10.4.3.2.

8.9.1. `inet`

The `inet` type holds an IPv4 or IPv6 host address, and optionally the identity of the subnet it is in, all
in one field. The subnet identity is represented by stating how many bits of the host address represent the network address (the “netmask”). If the netmask is 32 and the address is IPv4, then the value does not indicate a subnet, only a single host. In IPv6, the address length is 128 bits, so 128 bits specify a unique host address. Note that if you want to accept networks only, you should use the **cidr** type rather than **inet**.

The input format for this type is `address/y` where `address` is an IPv4 or IPv6 address and `y` is the number of bits in the netmask. If the `/y` part is left off, then the netmask is 32 for IPv4 and 128 for IPv6, so the value represents just a single host. On display, the `/y` portion is suppressed if the netmask specifies a single host.

### 8.9.2. cidr

The **cidr** type holds an IPv4 or IPv6 network specification. Input and output formats follow Classless Internet Domain Routing conventions. The format for specifying networks is `address/y` where `address` is the network represented as an IPv4 or IPv6 address, and `y` is the number of bits in the netmask. If `y` is omitted, it is calculated using assumptions from the older classful network numbering system, except that it will be at least large enough to include all of the octets written in the input. It is an error to specify a network address that has bits set to the right of the specified netmask.

Table 8-18 shows some examples.

**Table 8-18. cidr Type Input Examples**

<table>
<thead>
<tr>
<th>cidr Input</th>
<th>cidr Output</th>
<th>abbrev(cidr)</th>
</tr>
</thead>
<tbody>
<tr>
<td>192.168.100.128/25</td>
<td>192.168.100.128/25</td>
<td>192.168.100.128/25</td>
</tr>
<tr>
<td>192.168/24</td>
<td>192.168.0.0/24</td>
<td>192.168.0/24</td>
</tr>
<tr>
<td>192.168/25</td>
<td>192.168.0.0/25</td>
<td>192.168.0.0/25</td>
</tr>
<tr>
<td>192.168/1</td>
<td>192.168.1.0/24</td>
<td>192.168.1/24</td>
</tr>
<tr>
<td>192.168</td>
<td>192.168.0.0/24</td>
<td>192.168.0/24</td>
</tr>
<tr>
<td>128.1</td>
<td>128.1.0.0/16</td>
<td>128.1/16</td>
</tr>
<tr>
<td>128</td>
<td>128.0.0.0/16</td>
<td>128.0/16</td>
</tr>
<tr>
<td>128.1.2</td>
<td>128.1.2.0/24</td>
<td>128.1.2/24</td>
</tr>
<tr>
<td>10.1.2</td>
<td>10.1.2.0/24</td>
<td>10.1.2/24</td>
</tr>
<tr>
<td>10.1</td>
<td>10.1.0.0/16</td>
<td>10.1/16</td>
</tr>
<tr>
<td>10</td>
<td>10.0.0.0/8</td>
<td>10/8</td>
</tr>
<tr>
<td>10.1.2.3/32</td>
<td>10.1.2.3/32</td>
<td>10.1.2.3/32</td>
</tr>
<tr>
<td>2001:4f8:3:ba:/64</td>
<td>2001:4f8:3:ba:/64</td>
<td>2001:4f8:3:ba:/64</td>
</tr>
<tr>
<td>::ffff:1.2.3.0/120</td>
<td>::ffff:1.2.3.0/120</td>
<td>::ffff:1.2.3/120</td>
</tr>
<tr>
<td>::ffff:1.2.3.0/128</td>
<td>::ffff:1.2.3.0/128</td>
<td>::ffff:1.2.3.0/128</td>
</tr>
</tbody>
</table>

### 8.9.3. inet vs. cidr

The essential difference between **inet** and **cidr** data types is that **inet** accepts values with nonzero bits to the right of the netmask, whereas **cidr** does not.
Tip: If you do not like the output format for inet or cidr values, try the functions host, text, and abbrev.

8.9.4. macaddr

The macaddr type stores MAC addresses, i.e., Ethernet card hardware addresses (although MAC addresses are used for other purposes as well). Input is accepted in various customary formats, including

'08002b:010203'
'08002b-010203'
'0800.2b01.0203'
'08-00-2b-01-02-03'
'08:00:2b:01:02:03'

which would all specify the same address. Upper and lower case is accepted for the digits a through f. Output is always in the last of the forms shown.

8.10. Bit String Types

Bit strings are strings of 1’s and 0’s. They can be used to store or visualize bit masks. There are two SQL bit types: bit(n) and bit varying(n), where n is a positive integer.

Bit type data must match the length n exactly; it is an error to attempt to store shorter or longer bit strings. Bit varying data is of variable length up to the maximum length n; longer strings will be rejected. Writing bit without a length is equivalent to bit(1), while bit varying without a length specification means unlimited length.

Note: If one explicitly casts a bit-string value to bit(n), it will be truncated or zero-padded on the right to be exactly n bits, without raising an error. Similarly, if one explicitly casts a bit-string value to bit varying(n), it will be truncated on the right if it is more than n bits.

Refer to Section 4.1.2.3 for information about the syntax of bit string constants. Bit-logical operators and string manipulation functions are available; see Section 9.6.

Example 8-7. Using the bit string types

CREATE TABLE test (a BIT(3), b BIT VARYING(5));
INSERT INTO test VALUES (B’101’, B’00’);
INSERT INTO test VALUES (B’10’, B’101’);
ERROR: bit string length 2 does not match type bit(3)
INSERT INTO test VALUES (B’10’::bit(3), B’101’);
SELECT * FROM test;
a | b
-----+-----
101 | 00
100 | 101
Chapter 8. Data Types

A bit string value requires 1 byte for each group of 8 bits, plus 5 or 8 bytes overhead depending on the length of the string (but long values may be compressed or moved out-of-line, as explained in Section 8.3 for character strings).

8.11. Text Search Types

PostgreSQL provides two data types that are designed to support full text search, which is the activity of searching through a collection of natural-language documents to locate those that best match a query. The tsvector type represents a document in a form suited for text search, while the tsquery type similarly represents a query. Chapter 12 provides a detailed explanation of this facility, and Section 9.13 summarizes the related functions and operators.

8.11.1. tsvector

A tsvector value is a sorted list of distinct lexemes, which are words that have been normalized to make different variants of the same word look alike (see Chapter 12 for details). Sorting and duplicate-elimination are done automatically during input, as shown in this example:

```sql
SELECT 'a fat cat sat on a mat and ate a fat rat'::tsvector;
```

```
tsvecto
' a' 'on' 'and' 'ate' 'cat' 'fat' 'mat' 'rat' 'sat'
```

(As the example shows, the sorting is first by length and then alphabetically, but that detail is seldom important.) To represent lexemes containing whitespace or punctuation, surround them with quotes:

```sql
SELECT $$the lexeme ' ' contains spaces$$::tsvector;
```

```
tsvecto
' the' ' ' lexeme' 'spaces' 'contains'
```

(We use dollar-quoted string literals in this example and the next one, to avoid confusing matters by having to double quote marks within the literals.) Embedded quotes and backslashes must be doubled:

```sql
SELECT $$the lexeme 'Joe"s' contains a quote$$::tsvector;
```

```
tsvecto
'a' 'the' 'Joe"s' 'quote' 'lexeme' 'contains'
```

Optionally, integer position(s) can be attached to any or all of the lexemes:

```sql
SELECT 'a:1 fat:2 cat:3 sat:4 on:5 a:6 mat:7 and:8 ate:9 a:10 fat:11 rat:12'::tsvector;
```

```
tsvecto
'a':1,6,10 'on':5 'and':8 'ate':9 'cat':3 'fat':2,11 'mat':7 'rat':12 'sat':4
```

A position normally indicates the source word’s location in the document. Positional information can be used for proximity ranking. Position values can range from 1 to 16383; larger numbers are silently clamped to 16383. Duplicate positions for the same lexeme are discarded.

Lexemes that have positions can further be labeled with a weight, which can be A, B, C, or D. D is the default and hence is not shown on output:

```sql
SELECT 'a:1A fat:2B,4C cat:5D'::tsvector;
```
Weights are typically used to reflect document structure, for example by marking title words differently from body words. Text search ranking functions can assign different priorities to the different weight markers.

It is important to understand that the \texttt{tsvector} type itself does not perform any normalization; it assumes that the words it is given are normalized appropriately for the application. For example,

\begin{verbatim}
SELECT 'The Fat Rats'::tsvector;
\end{verbatim}

\begin{verbatim}
\texttt{tsvector}
\end{verbatim}

\begin{verbatim}
'Fat' 'The' 'Rats'
\end{verbatim}

For most English-text-searching applications the above words would be considered non-normalized, but \texttt{tsvector} doesn't care. Raw document text should usually be passed through \texttt{to_tsvector} to normalize the words appropriately for searching:

\begin{verbatim}
SELECT to_tsvector('english', 'The Fat Rats');
\end{verbatim}

\begin{verbatim}
\texttt{to_tsvector}
\end{verbatim}

\begin{verbatim}
'fat':2 'rat':3
\end{verbatim}

Again, see Chapter 12 for more detail.

\section{tsquery}

A \texttt{tsquery} value stores lexemes that are to be searched for, and combines them using the boolean operators $\&$ (AND), $|$ (OR), and $!$ (NOT). Parentheses can be used to enforce grouping of the operators:

\begin{verbatim}
SELECT 'fat & rat'::tsquery;
\end{verbatim}

\begin{verbatim}
\texttt{tsquery}
\end{verbatim}

\begin{verbatim}
'fat' & 'rat'
\end{verbatim}

\begin{verbatim}
SELECT 'fat & (rat | cat)'::tsquery;
\end{verbatim}

\begin{verbatim}
\texttt{tsquery}
\end{verbatim}

\begin{verbatim}
'fat' & ('rat' | 'cat')
\end{verbatim}

\begin{verbatim}
SELECT 'fat & rat & ! cat'::tsquery;
\end{verbatim}

\begin{verbatim}
\texttt{tsquery}
\end{verbatim}

\begin{verbatim}
'fat' & 'rat' & !'cat'
\end{verbatim}

In the absence of parentheses, ! (NOT) binds most tightly, and $\&$ (AND) binds more tightly than $|$ (OR).

Optionally, lexemes in a \texttt{tsquery} can be labeled with one or more weight letters, which restricts them to match only \texttt{tsvector} lexemes with one of those weights:

\begin{verbatim}
SELECT 'fat:ab & cat'::tsquery;
\end{verbatim}

\begin{verbatim}
\texttt{tsquery}
\end{verbatim}
Quoting rules for lexemes are the same as described above for lexemes in tsvector; and, as with tsvector, any required normalization of words must be done before putting them into the tsquery type. The to_tsquery function is convenient for performing such normalization:

```
SELECT to_tsquery('Fat:ab & Cats');
```

Output is always in the standard form.

PostgreSQL provides storage and comparison functions for UUIDs, but the core database does not include any function for generating UUIDs, because no single algorithm is well suited for every application. The contrib module contrib/uuid-ossp provides functions that implement several standard algorithms. Alternatively, UUIDs could be generated by client applications or other libraries invoked through a server-side function.

8.13. XML Type

The data type xml can be used to store XML data. Its advantage over storing XML data in a text field is that it checks the input values for well-formedness, and there are support functions to perform
type-safe operations on it; see Section 9.14. Use of this data type requires the installation to have been built with configure --with-libxml.

The xml type can store well-formed “documents”, as defined by the XML standard, as well as “content” fragments, which are defined by the production XMLDecl? content in the XML standard. Roughly, this means that content fragments can have more than one top-level element or character node. The expression xmlvalue IS DOCUMENT can be used to evaluate whether a particular xml value is a full document or only a content fragment.

### 8.13.1. Creating XML Values

To produce a value of type xml from character data, use the function xmlparse:

\[
\text{XMLPARSE ( \{ DOCUMENT | CONTENT \} value)}
\]

Examples:

XMLPARSE (DOCUMENT '<?xml version="1.0"?><book><title>Manual</title><chapter>...</chapter></book>')

XMLPARSE (CONTENT 'abc<foo>bar</foo><bar>foo</bar>')</n

While this is the only way to convert character strings into XML values according to the SQL standard, the PostgreSQL-specific syntaxes:

\[
\text{xml '<foo>bar</foo>''<foo>bar</foo>':'::xml}
\]

can also be used.

The xml type does not validate its input values against a possibly included document type declaration (DTD).

The inverse operation, producing character string type values from xml, uses the function xmlserialize:

\[
\text{XMLSERIALIZE ( \{ DOCUMENT | CONTENT \} value AS type )}
\]

type can be one of character, character varying, or text (or an alias name for those). Again, according to the SQL standard, this is the only way to convert between type xml and character types, but PostgreSQL also allows you to simply cast the value.

When character string values are cast to or from type xml without going through XMLPARSE or XMLSERIALIZE, respectively, the choice of DOCUMENT versus CONTENT is determined by the “XML option” session configuration parameter, which can be set using the standard command

\[
\text{SET XML OPTION \{ DOCUMENT | CONTENT \};}
\]

or the more PostgreSQL-like syntax

\[
\text{SET xmloption TO \{ DOCUMENT | CONTENT \};}
\]

The default is CONTENT, so all forms of XML data are allowed.

### 8.13.2. Encoding Handling

Care must be taken when dealing with multiple character encodings on the client, server, and in the XML data passed through them. When using the text mode to pass queries to the server and query
results to the client (which is the normal mode), PostgreSQL converts all character data passed between the client and the server and vice versa to the character encoding of the respective end; see Section 22.2. This includes string representations of XML values, such as in the above examples. This would ordinarily mean that encoding declarations contained in XML data might become invalid as the character data is converted to other encodings while travelling between client and server, while the embedded encoding declaration is not changed. To cope with this behavior, an encoding declaration contained in a character string presented for input to the xml type is ignored, and the content is always assumed to be in the current server encoding. Consequently, for correct processing, such character strings of XML data must be sent off from the client in the current client encoding. It is the responsibility of the client to either convert the document to the current client encoding before sending it off to the server or to adjust the client encoding appropriately. On output, values of type xml will not have an encoding declaration, and clients must assume that the data is in the current client encoding.

When using the binary mode to pass query parameters to the server and query results back to the client, no character set conversion is performed, so the situation is different. In this case, an encoding declaration in the XML data will be observed, and if it is absent, the data will be assumed to be in UTF-8 (as required by the XML standard; note that PostgreSQL does not support UTF-16 at all). On output, data will have an encoding declaration specifying the client encoding, unless the client encoding is UTF-8, in which case it will be omitted.

Needless to say, processing XML data with PostgreSQL will be less error-prone and more efficient if data encoding, client encoding, and server encoding are the same. Since XML data is internally processed in UTF-8, computations will be most efficient if the server encoding is also UTF-8.

### 8.13.3. Accessing XML Values

The xml data type is unusual in that it does not provide any comparison operators. This is because there is no well-defined and universally useful comparison algorithm for XML data. One consequence of this is that you cannot retrieve rows by comparing an xml column against a search value. XML values should therefore typically be accompanied by a separate key field such as an ID. An alternative solution for comparing XML values is to convert them to character strings first, but note that character string comparison has little to do with a useful XML comparison method.

Since there are no comparison operators for the xml data type, it is not possible to create an index directly on a column of this type. If speedy searches in XML data are desired, possible workarounds would be casting the expression to a character string type and indexing that, or indexing an XPath expression. The actual query would of course have to be adjusted to search by the indexed expression.

The text-search functionality in PostgreSQL could also be used to speed up full-document searches in XML data. The necessary preprocessing support is, however, not available in the PostgreSQL distribution in this release.

### 8.14. Arrays

PostgreSQL allows columns of a table to be defined as variable-length multidimensional arrays. Arrays of any built-in or user-defined base type, enum type, or composite type can be created. Arrays of domains are not yet supported.
8.14.1. Declaration of Array Types

To illustrate the use of array types, we create this table:

```sql
CREATE TABLE sal_emp (  
    name text,  
    pay_by_quarter integer[],  
    schedule text[][]
);
```

As shown, an array data type is named by appending square brackets ([ ]) to the data type name of the array elements. The above command will create a table named `sal_emp` with a column of type `text` (name), a one-dimensional array of type `integer` (pay_by_quarter), which represents the employee’s salary by quarter, and a two-dimensional array of `text` (schedule), which represents the employee’s weekly schedule.

The syntax for `CREATE TABLE` allows the exact size of arrays to be specified, for example:

```sql
CREATE TABLE tictactoe (  
    squares integer[3][3]
);
```

However, the current implementation does not enforce the array size limits — the behavior is the same as for arrays of unspecified length.

Actually, the current implementation does not enforce the declared number of dimensions either. Arrays of a particular element type are all considered to be of the same type, regardless of size or number of dimensions. So, declaring number of dimensions or sizes in `CREATE TABLE` is simply documentation, it does not affect run-time behavior.

An alternative syntax, which conforms to the SQL standard, can be used for one-dimensional arrays. `pay_by_quarter` could have been defined as:

```
    pay_by_quarter integer ARRAY[4],
```

This syntax requires an integer constant to denote the array size. As before, however, PostgreSQL does not enforce the size restriction.

8.14.2. Array Value Input

To write an array value as a literal constant, enclose the element values within curly braces and separate them by commas. (If you know C, this is not unlike the C syntax for initializing structures.) You can put double quotes around any element value, and must do so if it contains commas or curly braces. (More details appear below.) Thus, the general format of an array constant is the following:

```
'{ val1 delim val2 delim ... }'
```

where `delim` is the delimiter character for the type, as recorded in its `pg_type` entry. Among the standard data types provided in the PostgreSQL distribution, type `box` uses a semicolon (`;`) but all the others use comma (`,`). Each `val` is either a constant of the array element type, or a subarray. An example of an array constant is:

```
'{{1,2,3},{4,5,6},{7,8,9}}'
```

This constant is a two-dimensional, 3-by-3 array consisting of three subarrays of integers.
To set an element of an array constant to NULL, write NULL for the element value. (Any upper- or lower-case variant of NULL will do.) If you want an actual string value “NULL”, you must put double quotes around it.

(These kinds of array constants are actually only a special case of the generic type constants discussed in Section 4.1.2.5. The constant is initially treated as a string and passed to the array input conversion routine. An explicit type specification might be necessary.)

Now we can show some INSERT statements:

```sql
INSERT INTO sal_emp
VALUES ('Bill',
    '{10000, 10000, 10000, 10000}',
    '{{"meeting", "lunch"}, {"training", "presentation"}}');

INSERT INTO sal_emp
VALUES ('Carol',
    '{20000, 25000, 25000, 25000}',
    '{{"breakfast", "consulting"}, {"meeting", "lunch"}}');
```

The result of the previous two inserts looks like this:

```
SELECT * FROM sal_emp;
name | pay_by_quarter | schedule
-------+---------------------------+-------------------------------------------
Bill | {10000,10000,10000,10000} | {{meeting,lunch},{training,presentation}}
Carol | {20000,25000,25000,25000} | {{breakfast,consulting},{meeting,lunch}}
(2 rows)
```

The ARRAY constructor syntax can also be used:

```sql
INSERT INTO sal_emp
VALUES ('Bill',
    ARRAY[10000, 10000, 10000, 10000],
    ARRAY[{'meeting','lunch'}, {'training','presentation'}]);

INSERT INTO sal_emp
VALUES ('Carol',
    ARRAY[20000, 25000, 25000, 25000],
    ARRAY[{'breakfast','consulting'}, {'meeting','lunch'}]);
```

Notice that the array elements are ordinary SQL constants or expressions; for instance, string literals are single quoted, instead of double quoted as they would be in an array literal. The ARRAY constructor syntax is discussed in more detail in Section 4.2.10.

Multidimensional arrays must have matching extents for each dimension. A mismatch causes an error report, for example:

```sql
INSERT INTO sal_emp
VALUES ('Bill',
    '{10000, 10000, 10000, 10000}',
    '{{"meeting","lunch"}, {{"meeting"}}'});
ERROR:  multidimensional arrays must have array expressions with matching dimensions
```
8.14.3. Accessing Arrays

Now, we can run some queries on the table. First, we show how to access a single element of an array at a time. This query retrieves the names of the employees whose pay changed in the second quarter:

```
SELECT name FROM sal_emp WHERE pay_by_quarter[1] <> pay_by_quarter[2];
```

```
name
-----
Carol
(1 row)
```

The array subscript numbers are written within square brackets. By default PostgreSQL uses the one-based numbering convention for arrays, that is, an array of $n$ elements starts with $array[1]$ and ends with $array[n]$.

This query retrieves the third quarter pay of all employees:

```
SELECT pay_by_quarter[3] FROM sal_emp;
```

```
pay_by_quarter
----------------
 10000
 25000
(2 rows)
```

We can also access arbitrary rectangular slices of an array, or subarrays. An array slice is denoted by writing $lower-bound:upper-bound$ for one or more array dimensions. For example, this query retrieves the first item on Bill’s schedule for the first two days of the week:

```
SELECT schedule[1:2][1:1] FROM sal_emp WHERE name = 'Bill';
```

```
schedule
----------
{{meeting},{training}}
(1 row)
```

If any dimension is written as a slice, i.e. contains a colon, then all dimensions are treated as slices. Any dimension that has only a single number (no colon) is treated as being from 1 to the number specified. For example, $[2]$ is treated as $[1:2]$, as in this example:

```
SELECT schedule[1:2][2] FROM sal_emp WHERE name = 'Bill';
```

```
schedule
------------------------
{{meeting,lunch},{training,presentation}}
(1 row)
```

An array subscript expression will return null if either the array itself or any of the subscript expressions are null. Also, null is returned if a subscript is outside the array bounds (this case does not raise an error). For example, if $schedule$ currently has the dimensions $[1:3][1:2]$ then referencing $schedule[3][3]$ yields NULL. Similarly, an array reference with the wrong number of subscripts yields a null rather than an error.
An array slice expression likewise yields null if the array itself or any of the subscript expressions are null. However, in other corner cases such as selecting an array slice that is completely outside the current array bounds, a slice expression yields an empty (zero-dimensional) array instead of null. If the requested slice partially overlaps the array bounds, then it is silently reduced to just the overlapping region.

The current dimensions of any array value can be retrieved with the `array_dims` function:

```sql
SELECT array_dims(schedule) FROM sal_emp WHERE name = 'Carol';
```

```
array_dims
------------
[1:2][1:2]
(1 row)
```

`array_dims` produces a text result, which is convenient for people to read but perhaps not so convenient for programs. Dimensions can also be retrieved with `array_upper` and `array_lower`, which return the upper and lower bound of a specified array dimension, respectively:

```sql
SELECT array_upper(schedule, 1) FROM sal_emp WHERE name = 'Carol';
```

```
array_upper
------------
2
(1 row)
```

### 8.14.4. Modifying Arrays

An array value can be replaced completely:

```sql
UPDATE sal_emp SET pay_by_quarter = '{25000,25000,27000,27000}'
WHERE name = 'Carol';
```

or using the `ARRAY` expression syntax:

```sql
UPDATE sal_emp SET pay_by_quarter = ARRAY[25000,25000,27000,27000]
WHERE name = 'Carol';
```

An array can also be updated at a single element:

```sql
WHERE name = 'Bill';
```

or updated in a slice:

```sql
UPDATE sal_emp SET pay_by_quarter[1:2] = '{27000,27000}'
WHERE name = 'Carol';
```

A stored array value can be enlarged by assigning to element(s) not already present. Any positions between those previously present and the newly assigned element(s) will be filled with nulls. For example, if array `myarray` currently has 4 elements, it will have six elements after an update that assigns to `myarray[6]`, and `myarray[5]` will contain a null. Currently, enlargement in this fashion is only allowed for one-dimensional arrays, not multidimensional arrays.
Subscripted assignment allows creation of arrays that do not use one-based subscripts. For example one might assign to \texttt{myarray[-2:7]} to create an array with subscript values running from -2 to 7.

New array values can also be constructed by using the concatenation operator, \texttt{||}:

```sql
SELECT ARRAY[1,2] || ARRAY[3,4];
?column?
-----------
(1,2,3,4)
(1 row)

SELECT ARRAY[5,6] || ARRAY[[1,2],[3,4]];
?column?
---------------------
{{5,6},{1,2},{3,4}}
(1 row)
```

The concatenation operator allows a single element to be pushed on to the beginning or end of a one-dimensional array. It also accepts two \(N\)-dimensional arrays, or an \(N\)-dimensional and an \(N+1\)-dimensional array.

When a single element is pushed on to either the beginning or end of a one-dimensional array, the result is an array with the same lower bound subscript as the array operand. For example:

```sql
SELECT array_dims(1 || '1:0={2,3}'::int[]);
array_dims
------------
[0:2]
(1 row)

SELECT array_dims(ARRAY[1,2] || 3);
array_dims
------------
[1:3]
(1 row)
```

When two arrays with an equal number of dimensions are concatenated, the result retains the lower bound subscript of the left-hand operand’s outer dimension. The result is an array comprising every element of the left-hand operand followed by every element of the right-hand operand. For example:

```sql
SELECT array_dims(ARRAY[1,2] || ARRAY[3,4,5]);
array_dims
------------
[1:5]
(1 row)

SELECT array_dims(ARRAY[[1,2],[3,4]] || ARRAY[[5,6],[7,8],[9,0]]);
array_dims
------------
[1:5][1:2]
(1 row)
```
When an $N$-dimensional array is pushed on to the beginning or end of an $N+1$-dimensional array, the result is analogous to the element-array case above. Each $n$-dimensional sub-array is essentially an element of the $N+1$-dimensional array’s outer dimension. For example:

```sql
SELECT array_dims(ARRAY[1,2] || ARRAY[[3,4],[5,6]]);
array_dims
------------
[1:3][1:2]
(1 row)
```

An array can also be constructed by using the functions `array_prepend`, `array_append`, or `array_cat`. The first two only support one-dimensional arrays, but `array_cat` supports multidimensional arrays. Note that the concatenation operator discussed above is preferred over direct use of these functions. In fact, the functions exist primarily for use in implementing the concatenation operator. However, they might be directly useful in the creation of user-defined aggregates. Some examples:

```sql
SELECT array_prepend(1, ARRAY[2,3]);
array_prepend
---------------
{1,2,3}
(1 row)

SELECT array_append(ARRAY[1,2], 3);
array_append
---------------
{1,2,3}
(1 row)

SELECT array_cat(ARRAY[1,2], ARRAY[3,4]);
array_cat
---------
{1,2,3,4}
(1 row)

SELECT array_cat(ARRAY[[1,2],[3,4]], ARRAY[5,6]);
array_cat
---------
{{1,2},{3,4},{5,6}}
(1 row)

SELECT array_cat(ARRAY[5,6], ARRAY[[1,2],[3,4]]);
array_cat
---------
{{5,6},{1,2},{3,4}}
```

### 8.14.5. Searching in Arrays

To search for a value in an array, you must check each value of the array. This can be done by hand, if you know the size of the array. For example:

```sql
SELECT * FROM sal_emp WHERE pay_by_quarter[1] = 10000 OR
```

---

Page 122
However, this quickly becomes tedious for large arrays, and is not helpful if the size of the array is uncertain. An alternative method is described in Section 9.20. The above query could be replaced by:

```sql
SELECT * FROM sal_emp WHERE 10000 = ANY (pay_by_quarter);
```

In addition, you could find rows where the array had all values equal to 10000 with:

```sql
SELECT * FROM sal_emp WHERE 10000 = ALL (pay_by_quarter);
```

**Tip:** Arrays are not sets; searching for specific array elements can be a sign of database misdesign. Consider using a separate table with a row for each item that would be an array element. This will be easier to search, and is likely to scale up better to large numbers of elements.

### 8.14.6. Array Input and Output Syntax

The external text representation of an array value consists of items that are interpreted according to the I/O conversion rules for the array’s element type, plus decoration that indicates the array structure. The decoration consists of curly braces (\{ and \}) around the array value plus delimiter characters between adjacent items. The delimiter character is usually a comma (, ) but can be something else: it is determined by the `typdelim` setting for the array’s element type. (Among the standard data types provided in the PostgreSQL distribution, type `box` uses a semicolon (;) but all the others use comma.) In a multidimensional array, each dimension (row, plane, cube, etc.) gets its own level of curly braces, and delimiters must be written between adjacent curly-braced entities of the same level.

The array output routine will put double quotes around element values if they are empty strings, contain curly braces, delimiter characters, double quotes, backslashes, or white space, or match the word `NULL`. Double quotes and backslashes embedded in element values will be backslash-escaped. For numeric data types it is safe to assume that double quotes will never appear, but for textual data types one should be prepared to cope with either presence or absence of quotes.

By default, the lower bound index value of an array’s dimensions is set to one. To represent arrays with other lower bounds, the array subscript ranges can be specified explicitly before writing the array contents. This decoration consists of square brackets ([ ]) around each array dimension’s lower and upper bounds, with a colon (:) delimiter character in between. The array dimension decoration is followed by an equal sign (=). For example:

```sql
SELECT f1[1][-2][3] AS e1, f1[1][-1][5] AS e2
FROM (SELECT '[[1:1][-2:-1][3:5]=({{1,2,3},{4,5,6}})']::int[] AS f1) AS ss;
```

```
<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>6</td>
</tr>
</tbody>
</table>
```

The array output routine will include explicit dimensions in its result only when there are one or more lower bounds different from one.
If the value written for an element is `NULL` (in any case variant), the element is taken to be `NULL`. The presence of any quotes or backslashes disables this and allows the literal string value “NULL” to be entered. Also, for backwards compatibility with pre-8.2 versions of PostgreSQL, the `array_nulls` configuration parameter might be turned off to suppress recognition of `NULL` as a `NULL`.

As shown previously, when writing an array value you can write double quotes around any individual array element. You must do so if the element value would otherwise confuse the array-value parser. For example, elements containing curly braces, commas (or whatever the delimiter character is), double quotes, backslashes, or leading or trailing whitespace must be double-quoted. Empty strings and strings matching the word `NULL` must be quoted, too. To put a double quote or backslash in a quoted array element value, use escape string syntax and precede it with a backslash. Alternatively, you can use backslash-escaping to protect all data characters that would otherwise be taken as array syntax.

You can write whitespace before a left brace or after a right brace. You can also write whitespace before or after any individual item string. In all of these cases the whitespace will be ignored. However, whitespace within double-quoted elements, or surrounded on both sides by non-whitespace characters of an element, is not ignored.

**Note:** Remember that what you write in an SQL command will first be interpreted as a string literal, and then as an array. This doubles the number of backslashes you need. For example, to insert a `text` array value containing a backslash and a double quote, you'd need to write:

```sql
INSERT ... VALUES (E'"\","\"');
```

The escape string processor removes one level of backslashes, so that what arrives at the array-value parser looks like `{\\","\"}`. In turn, the strings fed to the `text` data type's input routine become \ and " respectively. (If we were working with a data type whose input routine also treated backslashes specially, `bytea`, for example, we might need as many as eight backslashes in the command to get one backslash into the stored array element.) Dollar quoting (see Section 4.1.2.2) can be used to avoid the need to double backslashes.

**Tip:** The `ARRAY` constructor syntax (see Section 4.2.10) is often easier to work with than the array-literal syntax when writing array values in SQL commands. In `ARRAY`, individual element values are written the same way they would be written when not members of an array.

### 8.15. Composite Types

A composite type describes the structure of a row or record; it is in essence just a list of field names and their data types. PostgreSQL allows values of composite types to be used in many of the same ways that simple types can be used. For example, a column of a table can be declared to be of a composite type.

#### 8.15.1. Declaration of Composite Types

Here are two simple examples of defining composite types:

```sql
CREATE TYPE complex AS (  
  r double precision,  
  i double precision
```
CREATE TYPE inventory_item AS (  name text,  supplier_id integer,  price numeric );

The syntax is comparable to CREATE TABLE, except that only field names and types can be specified; no constraints (such as NOT NULL) can presently be included. Note that the AS keyword is essential; without it, the system will think a quite different kind of CREATE TYPE command is meant, and you’ll get odd syntax errors.

Having defined the types, we can use them to create tables:

CREATE TABLE on_hand (  item inventory_item,  count integer );

INSERT INTO on_hand VALUES (ROW(’fuzzy dice’, 42, 1.99), 1000);

or functions:

CREATE FUNCTION price_extension(inventory_item, integer) RETURNS numeric AS ’SELECT $1.price * $2’ LANGUAGE SQL;

SELECT price_extension(item, 10) FROM on_hand;

Whenever you create a table, a composite type is also automatically created, with the same name as the table, to represent the table’s row type. For example, had we said:

CREATE TABLE inventory_item (  name text,  supplier_id integer REFERENCES suppliers,  price numeric CHECK (price > 0) );

then the same inventory_item composite type shown above would come into being as a byproduct, and could be used just as above. Note however an important restriction of the current implementation: since no constraints are associated with a composite type, the constraints shown in the table definition do not apply to values of the composite type outside the table. (A partial workaround is to use domain types as members of composite types.)

8.15.2. Composite Value Input

To write a composite value as a literal constant, enclose the field values within parentheses and separate them by commas. You can put double quotes around any field value, and must do so if it contains commas or parentheses. (More details appear below.) Thus, the general format of a composite constant is the following:

’( val1 , val2 , ... )’

An example is:
Chapter 8. Data Types

\[ \text{"fuzzy dice", 42, 1.99}\]

which would be a valid value of the `inventory_item` type defined above. To make a field be NULL,
write no characters at all in its position in the list. For example, this constant specifies a NULL third
field:

\[ \text{"fuzzy dice", 42,}\]

If you want an empty string rather than NULL, write double quotes:

\[ ", 42,\]

Here the first field is a non-NULL empty string, the third is NULL.

(These constants are actually only a special case of the generic type constants discussed in Section
4.1.2.5. The constant is initially treated as a string and passed to the composite-type input conversion
routine. An explicit type specification might be necessary.)

The `ROW` expression syntax can also be used to construct composite values. In most cases this is
considerably simpler to use than the string-literal syntax, since you don’t have to worry about multiple
layers of quoting. We already used this method above:

\begin{verbatim}
ROW\('fuzzy dice', 42, 1.99)  
ROW\('', 42, NULL)
\end{verbatim}

The `ROW` keyword is actually optional as long as you have more than one field in the expression, so
these can simplify to:

\begin{verbatim}
('fuzzy dice', 42, 1.99) 
('', 42, NULL)
\end{verbatim}

The `ROW` expression syntax is discussed in more detail in Section 4.2.11.

8.15.3. Accessing Composite Types

To access a field of a composite column, one writes a dot and the field name, much like selecting a
field from a table name. In fact, it’s so much like selecting from a table name that you often have to use
parentheses to keep from confusing the parser. For example, you might try to select some subfields
from our `on_hand` example table with something like:

\begin{verbatim}
SELECT item.name FROM on_hand WHERE item.price > 9.99;
\end{verbatim}

This will not work since the name `item` is taken to be a table name, not a field name, per SQL syntax
rules. You must write it like this:

\begin{verbatim}
SELECT (item).name FROM on_hand WHERE (item).price > 9.99;
\end{verbatim}

or if you need to use the table name as well (for instance in a multitable query), like this:

\begin{verbatim}
SELECT (on_hand.item).name FROM on_hand WHERE (on_hand.item).price > 9.99;
\end{verbatim}

Now the parenthesized object is correctly interpreted as a reference to the `item` column, and then the
subfield can be selected from it.

Similar syntactic issues apply whenever you select a field from a composite value. For instance, to
select just one field from the result of a function that returns a composite value, you’d need to write
something like:
SELECT (my_func(...)).field FROM ...

Without the extra parentheses, this will provoke a syntax error.

### 8.15.4. Modifying Composite Types

Here are some examples of the proper syntax for inserting and updating composite columns. First, inserting or updating a whole column:

```
INSERT INTO mytab (complex_col) VALUES((1.1,2.2));
```

```
UPDATE mytab SET complex_col = ROW(1.1,2.2) WHERE ...;
```

The first example omits ROW, the second uses it; we could have done it either way.

We can update an individual subfield of a composite column:

```
UPDATE mytab SET complex_col.r = (complex_col).r + 1 WHERE ...;
```

Notice here that we don’t need to (and indeed cannot) put parentheses around the column name appearing just after SET, but we do need parentheses when referencing the same column in the expression to the right of the equal sign.

And we can specify subfields as targets for INSERT, too:

```
INSERT INTO mytab (complex_col.r, complex_col.i) VALUES(1.1, 2.2);
```

Had we not supplied values for all the subfields of the column, the remaining subfields would have been filled with null values.

### 8.15.5. Composite Type Input and Output Syntax

The external text representation of a composite value consists of items that are interpreted according to the I/O conversion rules for the individual field types, plus decoration that indicates the composite structure. The decoration consists of parentheses ( ( and ) ) around the whole value, plus commas (,) between adjacent items. Whitespace outside the parentheses is ignored, but within the parentheses it is considered part of the field value, and might or might not be significant depending on the input conversion rules for the field data type. For example, in:

```
'( 42)'
```

the whitespace will be ignored if the field type is integer, but not if it is text.

As shown previously, when writing a composite value you can write double quotes around any individual field value. You must do so if the field value would otherwise confuse the composite-value parser. In particular, fields containing parentheses, commas, double quotes, or backslashes must be double-quoted. To put a double quote or backslash in a quoted composite field value, precede it with a backslash. (Also, a pair of double quotes within a double-quoted field value is taken to represent a double quote character, analogously to the rules for single quotes in SQL literal strings.) Alternatively, you can use backslash-escaping to protect all data characters that would otherwise be taken as composite syntax.

A completely empty field value (no characters at all between the commas or parentheses) represents a NULL. To write a value that is an empty string rather than NULL, write "".
Chapter 8. Data Types

The composite output routine will put double quotes around field values if they are empty strings or contain parentheses, commas, double quotes, backslashes, or white space. (Doing so for white space is not essential, but aids legibility.) Double quotes and backslashes embedded in field values will be doubled.

Note: Remember that what you write in an SQL command will first be interpreted as a string literal, and then as a composite. This doubles the number of backslashes you need (assuming escape string syntax is used). For example, to insert a text field containing a double quote and a backslash in a composite value, you’d need to write:

```
INSERT ... VALUES (E'("\\")');
```

The string-literal processor removes one level of backslashes, so that what arrives at the composite-value parser looks like "\". (If we were working with a data type whose input routine also treated backslashes specially, for example, we might need as many as eight backslashes in the command to get one backslash into the stored composite field.) Dollar quoting (see Section 4.1.2.2) can be used to avoid the need to double backslashes.

Tip: The ROW constructor syntax is usually easier to work with than the composite-literal syntax when writing composite values in SQL commands. In ROW, individual field values are written the same way they would be written when not members of a composite.

8.16. Object Identifier Types

Object identifiers (OIDs) are used internally by PostgreSQL as primary keys for various system tables. OIDs are not added to user-created tables, unless WITH OIDS is specified when the table is created, or the default_with_oids configuration variable is enabled. Type oid represents an object identifier. There are also several alias types for oid: regproc, regprocedure, regoper, regoperator, regclass, regtype, regconfig, and regdictionary. Table 8-19 shows an overview.

The oid type is currently implemented as an unsigned four-byte integer. Therefore, it is not large enough to provide database-wide uniqueness in large databases, or even in large individual tables. So, using a user-created table’s OID column as a primary key is discouraged. OIDs are best used only for references to system tables.

The oid type itself has few operations beyond comparison. It can be cast to integer, however, and then manipulated using the standard integer operators. (Beware of possible signed-versus-unsigned confusion if you do this.)

The OID alias types have no operations of their own except for specialized input and output routines. These routines are able to accept and display symbolic names for system objects, rather than the raw numeric value that type oid would use. The alias types allow simplified lookup of OID values for objects. For example, to examine the pg_attribute rows related to a table mytable, one could write:

```
SELECT * FROM pg_attribute WHERE attrelid = 'mytable':regclass;
```

rather than:

128
Chapter 8. Data Types

SELECT * FROM pg_attribute
WHERE attrelid = (SELECT oid FROM pg_class WHERE relname = 'mytable');

While that doesn’t look all that bad by itself, it’s still oversimplified. A far more complicated sub-
select would be needed to select the right OID if there are multiple tables named mytable in differ-
ent schemas. The regclass input converter handles the table lookup according to the schema path
setting, and so it does the “right thing” automatically. Similarly, casting a table’s OID to regclass
is handy for symbolic display of a numeric OID.

Table 8-19. Object Identifier Types

<table>
<thead>
<tr>
<th>Name</th>
<th>References</th>
<th>Description</th>
<th>Value Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>oid</td>
<td>any</td>
<td>numeric object identifier</td>
<td>564182</td>
</tr>
<tr>
<td>regproc</td>
<td>pg_proc</td>
<td>function name</td>
<td>sum</td>
</tr>
<tr>
<td>regprocedure</td>
<td>pg_proc</td>
<td>function with argument types</td>
<td>sum(int4)</td>
</tr>
<tr>
<td>regoper</td>
<td>pg_operator</td>
<td>operator name</td>
<td>+</td>
</tr>
<tr>
<td>regoperator</td>
<td>pg_operator</td>
<td>operator with argument types</td>
<td>*(integer,integer) or -(NONE,integer)</td>
</tr>
<tr>
<td>regclass</td>
<td>pg_class</td>
<td>relation name</td>
<td>pg_type</td>
</tr>
<tr>
<td>regtype</td>
<td>pg_type</td>
<td>data type name</td>
<td>integer</td>
</tr>
<tr>
<td>regconfig</td>
<td>pg_ts_config</td>
<td>text search configuration</td>
<td>english</td>
</tr>
<tr>
<td>regdictionary</td>
<td>pg_ts_dict</td>
<td>text search dictionary</td>
<td>simple</td>
</tr>
</tbody>
</table>

All of the OID alias types accept schema-qualified names, and will display schema-qualified names
on output if the object would not be found in the current search path without being qualified. The regproc
and regoper alias types will only accept input names that are unique (not overloaded),
so they are of limited use; for most uses regprocedure or regoperator is more appropriate. For regoperator, unary operators are identified by writing NONE for the unused operand.

An additional property of the OID alias types is that if a constant of one of these types appears in a
stored expression (such as a column default expression or view), it creates a dependency on the refer-
enced object. For example, if a column has a default expression nextval('my_seq'::regclass),
PostgreSQL understands that the default expression depends on the sequence my_seq; the system
will not let the sequence be dropped without first removing the default expression.

Another identifier type used by the system is xid, or transaction (abbreviated xact) identifier. This is
the data type of the system columns xmin and xmax. Transaction identifiers are 32-bit quantities.

A third identifier type used by the system is cid, or command identifier. This is the data type of the
system columns cmin and cmax. Command identifiers are also 32-bit quantities.

A final identifier type used by the system is tid, or tuple identifier (row identifier). This is the data
type of the system column ctid. A tuple ID is a pair (block number, tuple index within block) that
identifies the physical location of the row within its table.

(The system columns are further explained in Section 5.4.)
8.17. Pseudo-Types

The PostgreSQL type system contains a number of special-purpose entries that are collectively called pseudo-types. A pseudo-type cannot be used as a column data type, but it can be used to declare a function’s argument or result type. Each of the available pseudo-types is useful in situations where a function’s behavior does not correspond to simply taking or returning a value of a specific SQL data type. Table 8-20 lists the existing pseudo-types.

Table 8-20. Pseudo-Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>any</td>
<td>Indicates that a function accepts any input data type whatever.</td>
</tr>
<tr>
<td>anyarray</td>
<td>Indicates that a function accepts any array data type (see Section 34.2.5).</td>
</tr>
<tr>
<td>anyelement</td>
<td>Indicates that a function accepts any data type (see Section 34.2.5).</td>
</tr>
<tr>
<td>anyenum</td>
<td>Indicates that a function accepts any enum data type (see Section 34.2.5 and Section 8.7).</td>
</tr>
<tr>
<td>anynonarray</td>
<td>Indicates that a function accepts any non-array data type (see Section 34.2.5).</td>
</tr>
<tr>
<td>cstring</td>
<td>Indicates that a function accepts or returns a null-terminated C string.</td>
</tr>
<tr>
<td>internal</td>
<td>Indicates that a function accepts or returns a server-internal data type.</td>
</tr>
<tr>
<td>language_handler</td>
<td>A procedural language call handler is declared to return language_handler.</td>
</tr>
<tr>
<td>record</td>
<td>Identifies a function returning an unspecified row type.</td>
</tr>
<tr>
<td>trigger</td>
<td>A trigger function is declared to return trigger.</td>
</tr>
<tr>
<td>void</td>
<td>Indicates that a function returns no value.</td>
</tr>
<tr>
<td>opaque</td>
<td>An obsolete type name that formerly served all the above purposes.</td>
</tr>
</tbody>
</table>

Functions coded in C (whether built-in or dynamically loaded) can be declared to accept or return any of these pseudo data types. It is up to the function author to ensure that the function will behave safely when a pseudo-type is used as an argument type.

Functions coded in procedural languages can use pseudo-types only as allowed by their implementation languages. At present the procedural languages all forbid use of a pseudo-type as argument type, and allow only void and record as a result type (plus trigger when the function is used as a trigger). Some also support polymorphic functions using the types anyarray, anyelement, anyenum, and anynonarray.

The internal pseudo-type is used to declare functions that are meant only to be called internally by the database system, and not by direct invocation in a SQL query. If a function has at least one internal-type argument then it cannot be called from SQL. To preserve the type safety of this restriction it is important to follow this coding rule: do not create any function that is declared to return internal unless it has at least one internal argument.
Chapter 9. Functions and Operators

PostgreSQL provides a large number of functions and operators for the built-in data types. Users can also define their own functions and operators, as described in Part V. The psql commands \df and \do can be used to show the list of all actually available functions and operators, respectively.

If you are concerned about portability then take note that most of the functions and operators described in this chapter, with the exception of the most trivial arithmetic and comparison operators and some explicitly marked functions, are not specified by the SQL standard. Some of the extended functionality is present in other SQL database management systems, and in many cases this functionality is compatible and consistent between the various implementations. This chapter is also not exhaustive; additional functions appear in relevant sections of the manual.

9.1. Logical Operators

The usual logical operators are available:

```
AND
OR
NOT
```

SQL uses a three-valued Boolean logic where the null value represents “unknown”. Observe the following truth tables:

<table>
<thead>
<tr>
<th>a</th>
<th>b</th>
<th>a AND b</th>
<th>a OR b</th>
</tr>
</thead>
<tbody>
<tr>
<td>TRUE</td>
<td>TRUE</td>
<td>TRUE</td>
<td>TRUE</td>
</tr>
<tr>
<td>TRUE</td>
<td>FALSE</td>
<td>FALSE</td>
<td>TRUE</td>
</tr>
<tr>
<td>TRUE</td>
<td>NULL</td>
<td>NULL</td>
<td>TRUE</td>
</tr>
<tr>
<td>FALSE</td>
<td>FALSE</td>
<td>FALSE</td>
<td>FALSE</td>
</tr>
<tr>
<td>FALSE</td>
<td>NULL</td>
<td>FALSE</td>
<td>NULL</td>
</tr>
<tr>
<td>NULL</td>
<td>NULL</td>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>a</th>
<th>NOT a</th>
</tr>
</thead>
<tbody>
<tr>
<td>TRUE</td>
<td>FALSE</td>
</tr>
<tr>
<td>FALSE</td>
<td>TRUE</td>
</tr>
<tr>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

The operators AND and OR are commutative, that is, you can switch the left and right operand without affecting the result. But see Section 4.2.12 for more information about the order of evaluation of subexpressions.

9.2. Comparison Operators

The usual comparison operators are available, shown in Table 9-1.
Table 9-1. Comparison Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;</td>
<td>less than</td>
</tr>
<tr>
<td>&gt;</td>
<td>greater than</td>
</tr>
<tr>
<td>&lt;=</td>
<td>less than or equal to</td>
</tr>
<tr>
<td>&gt;=</td>
<td>greater than or equal to</td>
</tr>
<tr>
<td>=</td>
<td>equal</td>
</tr>
<tr>
<td>&lt;&gt; or !=</td>
<td>not equal</td>
</tr>
</tbody>
</table>

Note: The != operator is converted to <> in the parser stage. It is not possible to implement != and <> operators that do different things.

Comparison operators are available for all data types where this makes sense. All comparison operators are binary operators that return values of type boolean: expressions like \(1 < 2 < 3\) are not valid (because there is no < operator to compare a Boolean value with 3).

In addition to the comparison operators, the special BETWEEN construct is available.

\[ a \text{ BETWEEN } x \text{ AND } y \]

is equivalent to

\[ a \geq x \text{ AND } a \leq y \]

Similarly,

\[ a \text{ NOT BETWEEN } x \text{ AND } y \]

is equivalent to

\[ a < x \text{ OR } a > y \]

There is no difference between the two respective forms apart from the CPU cycles required to rewrite the first one into the second one internally. BETWEEN SYMMETRIC is the same as BETWEEN except there is no requirement that the argument to the left of AND be less than or equal to the argument on the right; the proper range is automatically determined.

To check whether a value is or is not null, use the constructs

\[ \text{expression IS NULL} \]
\[ \text{expression IS NOT NULL} \]

or the equivalent, but nonstandard, constructs

\[ \text{expression ISNULL} \]
\[ \text{expression NOTNULL} \]

Do not write \[ \text{expression = NULL} \] because NULL is not “equal to” NULL. (The null value represents an unknown value, and it is not known whether two unknown values are equal.) This behavior conforms to the SQL standard.
Tip: Some applications might expect that \texttt{expression} = \texttt{NULL} returns true if \texttt{expression} evaluates to the null value. It is highly recommended that these applications be modified to comply with the SQL standard. However, if that cannot be done the transform\_null\_equals configuration variable is available. If it is enabled, PostgreSQL will convert \texttt{x = NULL} clauses to \texttt{x IS NULL}. This was the default behavior in PostgreSQL releases 6.5 through 7.1.

Note: If the \textit{expression} is row-valued, then \texttt{IS NULL} is true when the row expression itself is null or when all the row's fields are null, while \texttt{IS NOT NULL} is true when the row expression itself is non-null and all the row's fields are non-null. This definition conforms to the SQL standard, and is a change from the inconsistent behavior exhibited by PostgreSQL versions prior to 8.2.

The ordinary comparison operators yield null (signifying “unknown”) when either input is null. Another way to do comparisons is with the \texttt{IS \ [ NOT \ ] DISTINCT FROM} construct:

\begin{align*}
\texttt{expression IS DISTINCT FROM expression} \\
\texttt{expression IS NOT DISTINCT FROM expression}
\end{align*}

For non-null inputs, \texttt{IS DISTINCT FROM} is the same as the \texttt{<>} operator. However, when both inputs are null it will return false, and when just one input is null it will return true. Similarly, \texttt{IS NOT DISTINCT FROM} is identical to \texttt{=} for non-null inputs, but it returns true when both inputs are null, and false when only one input is null. Thus, these constructs effectively act as though null were a normal data value, rather than “unknown”.

Boolean values can also be tested using the constructs

\begin{align*}
\texttt{expression IS TRUE} \\
\texttt{expression IS NOT TRUE} \\
\texttt{expression IS FALSE} \\
\texttt{expression IS NOT FALSE} \\
\texttt{expression IS UNKNOWN} \\
\texttt{expression IS NOT UNKNOWN}
\end{align*}

These will always return true or false, never a null value, even when the operand is null. A null input is treated as the logical value “unknown”. Notice that \texttt{IS UNKNOWN} and \texttt{IS NOT UNKNOWN} are effectively the same as \texttt{IS NULL} and \texttt{IS NOT NULL}, respectively, except that the input expression must be of Boolean type.

### 9.3. Mathematical Functions and Operators

Mathematical operators are provided for many PostgreSQL types. For types without common mathematical conventions for all possible permutations (e.g., date/time types) we describe the actual behavior in subsequent sections.

Table 9-2 shows the available mathematical operators.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>

<td>16</td>
</tr>
<tr>
<td>&gt;&gt;</td>
<td>bitwise shift right</td>
<td>$8 &gt;&gt; 2$</td>
<td>2</td>
</tr>
</tbody>
</table>

The bitwise operators work only on integral data types, whereas the others are available for all numeric data types. The bitwise operators are also available for the bit string types `bit` and `bit varying`, as shown in Table 9-10.

Table 9-3 shows the available mathematical functions. In the table, `dp` indicates `double precision`. Many of these functions are provided in multiple forms with different argument types. Except where noted, any given form of a function returns the same data type as its argument. The functions working with `double precision` data are mostly implemented on top of the host system’s `C` library; accuracy and behavior in boundary cases can therefore vary depending on the host system.

### Table 9-3. Mathematical Functions

<td>tangent</td>
</tr>
</tbody>
</table>

9.4. String Functions and Operators

This section describes functions and operators for examining and manipulating string values. Strings in this context include values of the types `character`, `character varying`, and `text`. Unless otherwise noted, all of the functions listed below work on all of these types, but be wary of potential effects of automatic space-padding when using the `character` type. Some functions also exist natively for the bit-string types.

SQL defines some string functions with a special syntax wherein certain key words rather than commas are used to separate the arguments. Details are in Table 9-5. These functions are also implemented using the regular syntax for function invocation. (See Table 9-6.)

**Note:** Before PostgreSQL 8.3, these functions would silently accept values of several non-string data types as well, due to the presence of implicit coercions from those data types to `text`. Those coercions have been removed because they frequently caused surprising behaviors. However,
the string concatenation operator (||) still accepts non-string input, so long as at least one input is of a string type, as shown in Table 9-5. For other cases, insert an explicit coercion to text if you need to duplicate the previous behavior.

Table 9-5. SQL String Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Return Type</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>string</td>
<td></td>
<td>string</td>
<td>text</td>
<td>String concatenation</td>
</tr>
<tr>
<td>string</td>
<td></td>
<td>non-string</td>
<td>text</td>
<td>String concatenation with one non-string input</td>
</tr>
<tr>
<td>bit_length(string)</td>
<td>int</td>
<td>Number of bits in string</td>
<td>bit_length('jose')</td>
<td>32</td>
</tr>
<tr>
<td>char_length(string)</td>
<td>int</td>
<td>Number of characters in string</td>
<td>char_length('jose')</td>
<td>4</td>
</tr>
<tr>

<tr>
<td>octet_length(string)</td>
<td>int</td>
<td>Number of bytes in string</td>
<td>octet_length('jose')</td>
<td>4</td>
</tr>
<tr>
<td>overlay(string placing string from int [for int])</td>
<td>text</td>
<td>Replace substring</td>
<td>overlay('Txxxxas' placing 'hom' from 2 for 4)</td>
<td>Thomas</td>
</tr>
<tr>
<td>position(substring in string)</td>
<td>int</td>
<td>Location of specified substring</td>
<td>position('om' in 'Thomas')</td>
<td>3</td>
</tr>
<tr>
<td>substring(string [from int] [for int])</td>
<td>text</td>
<td>Extract substring</td>
<td>substring('Thomas' from 2 for 3)</td>
<td>hom</td>
</tr>
<tr>
<td>substring(string from pattern)</td>
<td>text</td>
<td>Extract substring matching POSIX regular expression. See Section 9.7 for more information on pattern matching.</td>
<td>substring('Thomas' from '...$')</td>
<td>Thomas</td>
</tr>
</tbody>
</table>
### Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Return Type</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>substring(string</td>
<td>text</td>
<td>Extract substring matching SQL regular expression. See Section 9.7 for</td>
<td>substring('Thomas' from '%'</td>
<td>oma</td>
</tr>
<tr>
<td>from pattern</td>
<td></td>
<td>more information on pattern matching.</td>
<td>'%&quot;o_a&quot;%' for '#'</td>
<td></td>
</tr>
<tr>
<td>for escape)</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>trim([leading</td>
<td>text</td>
<td>Remove the longest string containing only the characters (a space by</td>
<td>trim(both 'x' from 'xTomxx')</td>
<td>Tom</td>
</tr>
<tr>
<td></td>
<td>trailing</td>
<td></td>
<td>default) from the start/end/both ends of the string</td>
<td></td>
</tr>
<tr>

**Notes:**

a. The conversion names follow a standard naming scheme: The official name of the source encoding with all non-alphanumeric characters replaced by underscores followed by _to_ followed by the equally processed destination encoding name. Therefore the names might deviate from the customary encoding names.
9.5. Binary String Functions and Operators

This section describes functions and operators for examining and manipulating values of type `bytea`. SQL defines some string functions with a special syntax where certain key words rather than commas are used to separate the arguments. Details are in Table 9-8. Some functions are also implemented using the regular syntax for function invocation. (See Table 9-9.)

Table 9-8. SQL Binary String Functions and Operators

</tr>
</tbody>
</table>

Additional binary string manipulation functions are available and are listed in Table 9-9. Some of them are used internally to implement the SQL-standard string functions listed in Table 9-8.

Table 9-9. Other Binary String Functions

<table>
<thead>

</tr>
</thead>
</table>
### 9.6. Bit String Functions and Operators

This section describes functions and operators for examining and manipulating bit strings, that is, values of the types \texttt{bit} and \texttt{bit varying}. Aside from the usual comparison operators, the operators shown in Table 9-10 can be used. Bit string operands of \&, |, and \# must be of equal length. When bit shifting, the original length of the string is preserved, as shown in the examples.

#### Table 9-10. Bit String Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>||</td>
<td>concatenation</td>
<td>\texttt{B’10001’</td>
<td></td>
</tr>
<tr>

<td>bitwise AND</td>
<td>\texttt{B’10001’ &amp; B’01101’}</td>
<td>00001</td>
</tr>
<tr>
<td></td>
<td></td>
<td>bitwise OR</td>
<td>\texttt{B’10001’</td>
</tr>
</tbody>
</table>
## Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>#</td>
<td>bitwise XOR</td>
<td>B'10001' #</td>
<td>11100</td>
</tr>
<tr>
<td>~</td>
<td>bitwise NOT</td>
<td>~ B'10001'</td>
<td>01110</td>
</tr>
<tr>
<td>&lt;&lt;</td>
<td>bitwise shift left</td>
<td>B'10001' &lt;&lt; 3</td>
<td>01000</td>
</tr>
<tr>
<td>&gt;&gt;</td>
<td>bitwise shift right</td>
<td>B'10001' &gt;&gt; 2</td>
<td>00100</td>
</tr>
</tbody>
</table>

The following SQL-standard functions work on bit strings as well as character strings: `length`, `bit_length`, `octet_length`, `position`, `substring`.

In addition, it is possible to cast integral values to and from type `bit`. Some examples:

```
44::bit(10)       0000101100
44::bit(3)        100
cast(-44 as bit(12)) 111111010100
'1110)::bit(4)::integer 14
```

Note that casting to just “bit” means casting to `bit(1)`, and so it will deliver only the least significant bit of the integer.

**Note:** Prior to PostgreSQL 8.0, casting an integer to `bit(n)` would copy the leftmost `n` bits of the integer, whereas now it copies the rightmost `n` bits. Also, casting an integer to a bit string width wider than the integer itself will sign-extend on the left.

### 9.7. Pattern Matching

There are three separate approaches to pattern matching provided by PostgreSQL: the traditional SQL `LIKE` operator, the more recent `SIMILAR TO` operator (added in SQL:1999), and POSIX-style regular expressions. Aside from the basic “does this string match this pattern?” operators, functions are available to extract or replace matching substrings and to split a string at the matches.

**Tip:** If you have pattern matching needs that go beyond this, consider writing a user-defined function in Perl or Tcl.

#### 9.7.1. LIKE

```
string LIKE pattern [ESCAPE escape-character]
string NOT LIKE pattern [ESCAPE escape-character]
```

Every `pattern` defines a set of strings. The `LIKE` expression returns true if the `string` is contained in the set of strings represented by `pattern`. (As expected, the `NOT LIKE` expression returns false if `LIKE` returns true, and vice versa. An equivalent expression is `NOT (string LIKE pattern).`)

If `pattern` does not contain percent signs or underscore, then the pattern only represents the string itself; in that case `LIKE` acts like the equals operator. An underscore (_) in `pattern` stands for (matches) any single character; a percent sign (%) matches any string of zero or more characters.

Some examples:
LIKE pattern matches always cover the entire string. To match a sequence anywhere within a string, the pattern must therefore start and end with a percent sign.

To match a literal underscore or percent sign without matching other characters, the respective character in pattern must be preceded by the escape character. The default escape character is the backslash but a different one can be selected by using the ESCAPE clause. To match the escape character itself, write two escape characters.

Note that the backslash already has a special meaning in string literals, so to write a pattern constant that contains a backslash you must write two backslashes in an SQL statement (assuming escape string syntax is used, see Section 4.1.2.1). Thus, writing a pattern that actually matches a literal backslash means writing four backslashes in the statement. You can avoid this by selecting a different escape character with ESCAPE; then a backslash is not special to LIKE anymore. (But it is still special to the string literal parser, so you still need two of them.)

It’s also possible to select no escape character by writing ESCAPE ". This effectively disables the escape mechanism, which makes it impossible to turn off the special meaning of underscore and percent signs in the pattern.

The key word ILIKE can be used instead of LIKE to make the match case-insensitive according to the active locale. This is not in the SQL standard but is a PostgreSQL extension.

The operator ~~~ is equivalent to LIKE, and ~~~* corresponds to ILIKE. There are also !~~ and !~~* operators that represent NOT LIKE and NOT ILIKE, respectively. All of these operators are PostgreSQL-specific.

### 9.7.2. SIMILAR TO Regular Expressions

`string SIMILAR TO pattern [ESCAPE escape-character]`

`string NOT SIMILAR TO pattern [ESCAPE escape-character]`

The SIMILAR TO operator returns true or false depending on whether its pattern matches the given string. It is much like LIKE, except that it interprets the pattern using the SQL standard’s definition of a regular expression. SQL regular expressions are a curious cross between LIKE notation and common regular expression notation.

Like LIKE, the SIMILAR TO operator succeeds only if its pattern matches the entire string; this is unlike common regular expression practice, wherein the pattern can match any part of the string. Also like LIKE, SIMILAR TO uses _ and % as wildcard characters denoting any single character and any string, respectively (these are comparable to . and .* in POSIX regular expressions).

In addition to these facilities borrowed from LIKE, SIMILAR TO supports these pattern-matching metacharacters borrowed from POSIX regular expressions:

- | denotes alternation (either of two alternatives).
- * denotes repetition of the previous item zero or more times.
- + denotes repetition of the previous item one or more times.
- Parentheses () can be used to group items into a single logical item.
• A bracket expression [ . . .] specifies a character class, just as in POSIX regular expressions.

Notice that bounded repetition ( ? and { . . .}) are not provided, though they exist in POSIX. Also, the
dot ( .) is not a metacharacter.

As with LIKE, a backslash disables the special meaning of any of these metacharacters; or a different
escape character can be specified with ESCAPE.

Some examples:

'abc' SIMILAR TO 'abc'  true
'abc' SIMILAR TO 'a'  false
'abc' SIMILAR TO '%(b|d)%'  true
'abc' SIMILAR TO '(b|c)%'  false

The substring function with three parameters, substring(string from pattern for
escape-character), provides extraction of a substring that matches an SQL regular expression
pattern. As with SIMILAR TO, the specified pattern must match to the entire data string, else the
function fails and returns null. To indicate the part of the pattern that should be returned on success,
the pattern must contain two occurrences of the escape character followed by a double quote (%). The
text matching the portion of the pattern between these markers is returned.

Some examples:

substring('foobar' from '%"o_b"%' for '#')  oob
substring('foobar' from '#"o_b"%' for '#')  NULL

9.7.3. POSIX Regular Expressions

Table 9-11 lists the available operators for pattern matching using POSIX regular expressions.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>~</td>
<td>Matches regular expression, case sensitive</td>
<td>'thomas' ~ '.<em>thomas.</em>'</td>
</tr>
<tr>
<td>~*</td>
<td>Matches regular expression, case insensitive</td>
<td>'thomas' ~* '.<em>Thomas.</em>'</td>
</tr>
<tr>
<td>!~</td>
<td>Does not match regular expression, case sensitive</td>
<td>'thomas' !~ '.<em>Thomas.</em>'</td>
</tr>
<tr>
<td>!~*</td>
<td>Does not match regular expression, case insensitive</td>
<td>'thomas' !~* '.<em>vadim.</em>'</td>
</tr>
</tbody>
</table>

POSIX regular expressions provide a more powerful means for pattern matching than the LIKE and
SIMILAR TO operators. Many Unix tools such as egrep, sed, or awk use a pattern matching language
that is similar to the one described here.

A regular expression is a character sequence that is an abbreviated definition of a set of strings (a
regular set). A string is said to match a regular expression if it is a member of the regular set described
by the regular expression. As with LIKE, pattern characters match string characters exactly unless
they are special characters in the regular expression language — but regular expressions use different
special characters than LIKE does. Unlike LIKE patterns, a regular expression is allowed to match anywhere within a string, unless the regular expression is explicitly anchored to the beginning or end of the string.

Some examples:

'abc' ~ 'abc'    true
'abc' ~ '^a'     true
'abc' ~ '(b|d)'  true
'abc' ~ '^'(b|c) false

The POSIX pattern language is described in much greater detail below.

The substring function with two parameters, substring(string from pattern), provides extraction of a substring that matches a POSIX regular expression pattern. It returns null if there is no match, otherwise the portion of the text that matched the pattern. But if the pattern contains any parentheses, the portion of the text that matched the first parenthesized subexpression (the one whose left parenthesis comes first) is returned. You can put parentheses around the whole expression if you want to use parentheses within it without triggering this exception. If you need parentheses in the pattern before the subexpression you want to extract, see the non-capturing parentheses described below.

Some examples:

substring('foobar' from 'o.b')    oob
substring('foobar' from 'o(.)b')   o

The regexp_replace function provides substitution of new text for substrings that match POSIX regular expression patterns. It has the syntax regexp_replace(source, pattern, replacement []). The source string is returned unchanged if there is no match to the pattern. If there is a match, the source string is returned with the replacement string substituted for the matching substring. The replacement string can contain \n, where n is 1 through 9, to indicate that the source substring matching the n’th parenthesized subexpression of the pattern should be inserted, and it can contain \ to indicate that the substring matching the entire pattern should be inserted. Write \ if you need to put a literal backslash in the replacement text. (As always, remember to double backslashes written in literal constant strings, assuming escape string syntax is used.) The flags parameter is an optional text string containing zero or more single-letter flags that change the function’s behavior. Flag i specifies case-insensitive matching, while flag g specifies replacement of each matching substring rather than only the first one. Other supported flags are described in Table 9-19.

Some examples:

regexp_replace('foobarbaz', 'b..', 'X')    fooXbaz
regexp_replace('foobarbaz', 'b..', 'X', 'g') fooXX
regexp_replace('foobarbaz', 'b(...)', E'X\1Y', 'g') fooXarYXazY

The regexp_matches function returns all of the captured substrings resulting from matching a POSIX regular expression pattern. It has the syntax regexp_matches(string, pattern [, flags ]). If there is no match to the pattern, the function returns no rows. If there is a match, the function returns a text array whose n’th element is the substring matching the n’th parenthesized subexpression
of the pattern (not counting “non-capturing” parentheses; see below for details). If the pattern does
not contain any parenthesized subexpressions, then the result is a single-element text array containing
the substring matching the whole pattern. The flags parameter is an optional text string containing
zero or more single-letter flags that change the function’s behavior. Flag g causes the function to find
each match in the string, not only the first one, and return a row for each such match. Other supported
flags are described in Table 9-19.

Some examples:

```sql
SELECT regexp_matches('foobardequebaz', '(bar)(beque)');
regexp_matches
----------------
{bar,beque}
(1 row)
```

```sql
SELECT regexp_matches('foobardequebazilbarfbonk', '(b[^b]+)(b[^b]+)', 'g');
regexp_matches
----------------
{bar,beque}
{bazil,barf}
(2 rows)
```

```sql
SELECT regexp_matches('foobardequebaz', 'barbeque');
regexp_matches
----------------
{barbeque}
(1 row)
```

The `regexp_split_to_table` function splits a string using a POSIX regular expression pattern as
a delimiter. It has the syntax `regexp_split_to_table(string, pattern [, flags ])`. If there is
no match to the pattern, the function returns the string. If there is at least one match, for each
match it returns the text from the end of the last match (or the beginning of the string) to the beginning
of the match. When there are no more matches, it returns the text from the end of the last match to the
end of the string. The flags parameter is an optional text string containing zero or more single-letter
flags that change the function’s behavior. `regexp_split_to_table` supports the flags described in
Table 9-19.

The `regexp_split_to_array` function behaves the same as `regexp_split_to_table`,
except that `regexp_split_to_array` returns its result as an array of text. It has the syntax
`regexp_split_to_array(string, pattern [, flags ])`. The parameters are the same as for
`regexp_split_to_table`.

Some examples:

```sql
SELECT foo FROM regexp_split_to_table('the quick brown fox jumped over the lazy dog', E'\s+');
foo
--------
the
quick
brown
fox
jumped
over
the
lazy
dog
```

---

154
As the last example demonstrates, the regexp split functions ignore zero-length matches that occur at the start or end of the string or immediately after a previous match. This is contrary to the strict definition of regexp matching that is implemented by \texttt{regexp_matches}, but is usually the most convenient behavior in practice. Other software systems such as Perl use similar definitions.

### 9.7.3.1. Regular Expression Details

PostgreSQL’s regular expressions are implemented using a package written by Henry Spencer. Much of the description of regular expressions below is copied verbatim from his manual entry.

Regular expressions (REs), as defined in POSIX 1003.2, come in two forms: \textit{extended} REs or EREs (roughly those of egrep), and \textit{basic} REs or BREs (roughly those of ed). PostgreSQL supports both forms, and also implements some extensions that are not in the POSIX standard, but have become widely used anyway due to their availability in programming languages such as Perl and Tcl. REs using these non-POSIX extensions are called \textit{advanced} REs or AREs in this documentation. AREs are almost an exact superset of EREs, but BREs have several notational incompatibilities (as well as being much more limited). We first describe the ARE and ERE forms, noting features that apply only to AREs, and then describe how BREs differ.

\textbf{Note:} The form of regular expressions accepted by PostgreSQL can be chosen by setting the \texttt{regex_flavor} run-time parameter. The usual setting is \texttt{advanced}, but one might choose \texttt{extended} for maximum backwards compatibility with pre-7.4 releases of PostgreSQL.
A regular expression is defined as one or more branches, separated by \|. It matches anything that matches one of the branches.

A branch is zero or more quantified atoms or constraints, concatenated. It matches a match for the first, followed by a match for the second, etc; an empty branch matches the empty string.

A quantified atom is an atom possibly followed by a single quantifier. Without a quantifier, it matches a match for the atom. With a quantifier, it can match some number of matches of the atom. An atom can be any of the possibilities shown in Table 9-12. The possible quantifiers and their meanings are shown in Table 9-13.

A constraint matches an empty string, but matches only when specific conditions are met. A constraint can be used where an atom could be used, except it cannot be followed by a quantifier. The simple constraints are shown in Table 9-14; some more constraints are described later.

### Table 9-12. Regular Expression Atoms

<table>
<thead>
<tr>
<th>Atom</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>(re)</td>
<td>(where re is any regular expression) matches a match for re, with the match noted for possible reporting</td>
</tr>
<tr>
<td>(?:re)</td>
<td>as above, but the match is not noted for reporting (a “non-capturing” set of parentheses) (AREs only)</td>
</tr>
<tr>
<td>.</td>
<td>matches any single character</td>
</tr>
<tr>
<td>[chars]</td>
<td>a bracket expression, matching any one of the chars (see Section 9.7.3.2 for more detail)</td>
</tr>
<tr>
<td>\k</td>
<td>(where k is a non-alphanumeric character) matches that character taken as an ordinary character, e.g. \ \ matches a backslash character</td>
</tr>
<tr>
<td>\c</td>
<td>where c is alphanumeric (possibly followed by other characters) is an escape, see Section 9.7.3.3 (AREs only; in EREs and BREs, this matches c)</td>
</tr>
<tr>
<td>{</td>
<td>when followed by a character other than a digit, matches the left-brace character ; when followed by a digit, it is the beginning of a bound (see below)</td>
</tr>
<tr>
<td>x</td>
<td>where x is a single character with no other significance, matches that character</td>
</tr>
</tbody>
</table>

An RE cannot end with \. 

**Note:** Remember that the backslash (\) already has a special meaning in PostgreSQL string literals. To write a pattern constant that contains a backslash, you must write two backslashes in the statement, assuming escape string syntax is used (see Section 4.1.2.1).

### Table 9-13. Regular Expression Quantifiers

<table>
<thead>
<tr>
<th>Quantifier</th>
<th>Matches</th>
</tr>
</thead>
</table>

156
Quantifier | Matches
---|---
* | a sequence of 0 or more matches of the atom
+ | a sequence of 1 or more matches of the atom
? | a sequence of 0 or 1 matches of the atom
\{m\} | a sequence of exactly \(m\) matches of the atom
\{m,\} | a sequence of \(m\) or more matches of the atom
\{m, n\} | a sequence of \(m\) through \(n\) (inclusive) matches of the atom; \(m\) cannot exceed \(n\)
*? | non-greedy version of *
+? | non-greedy version of +
?? | non-greedy version of ?
\{m\}? | non-greedy version of \{m\}
\{m,\}? | non-greedy version of \{m,\}
\{m, n\}? | non-greedy version of \{m, n\}

The forms using \{...\} are known as **bounds**. The numbers \(m\) and \(n\) within a bound are unsigned decimal integers with permissible values from 0 to 255 inclusive.

**Non-greedy** quantifiers (available in AREs only) match the same possibilities as their corresponding normal (greedy) counterparts, but prefer the smallest number rather than the largest number of matches. See Section 9.7.3.5 for more detail.

**Note:** A quantifier cannot immediately follow another quantifier. A quantifier cannot begin an expression or subexpression or follow ^ or |.

### Table 9-14. Regular Expression Constraints

<table>
<thead>
<tr>
<th>Constraint</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>^</td>
<td>matches at the beginning of the string</td>
</tr>
<tr>
<td>$</td>
<td>matches at the end of the string</td>
</tr>
<tr>
<td>((?=xe))</td>
<td><em>positive lookahead</em> matches at any point where a substring matching (xe) begins (AREs only)</td>
</tr>
<tr>
<td>((?!xe))</td>
<td><em>negative lookahead</em> matches at any point where no substring matching (xe) begins (AREs only)</td>
</tr>
</tbody>
</table>

Lookahead constraints cannot contain back references (see Section 9.7.3.3), and all parentheses within them are considered non-capturing.

#### 9.7.3.2. Bracket Expressions

A **bracket expression** is a list of characters enclosed in \[\]. It normally matches any single character from the list (but see below). If the list begins with ^, it matches any single character not from the rest of the list. If two characters in the list are separated by -, this is shorthand for the full range of characters between those two (inclusive) in the collating sequence, e.g. [0-9] in ASCII matches any decimal digit. It is illegal for two ranges to share an endpoint, e.g. a-c-e. Ranges are very collating-sequence-dependent, so portable programs should avoid relying on them.
To include a literal ] in the list, make it the first character (following a possible ^). To include a literal ^, make it the first or last character, or the second endpoint of a range. To use a literal ^ as the first endpoint of a range, enclose it in [ and ] to make it a collating element (see below). With the exception of these characters, some combinations using ] (see next paragraphs), and escapes (AREs only), all other special characters lose their special significance within a bracket expression. In particular, \ is not special when following ERE or BRE rules, though it is special (as introducing an escape) in AREs.

Within a bracket expression, a collating element (a character, a multiple-character sequence that collates as if it were a single character, or a collating-sequence name for either) enclosed in [ and ] stands for the sequence of characters of that collating element. The sequence is a single element of the bracket expression’s list. A bracket expression containing a multiple-character collating element can thus match more than one character, e.g. if the collating sequence includes a ch collating element, then the RE [ [.ch. ]] matches the first five characters of chchcc.

Note: PostgreSQL currently has no multicharacter collating elements. This information describes possible future behavior.

Within a bracket expression, a collating element enclosed in [ = and = ] is an equivalence class, standing for the sequences of characters of all collating elements equivalent to that one, including itself. (If there are no other equivalent collating elements, the treatment is as if the enclosing delimiters were [ and ]). For example, if o and ^ are the members of an equivalence class, then [ [ = o = ] ] , [ [ = ^ = ] ] , and [ o ^ ] are all synonymous. An equivalence class cannot be an endpoint of a range.

Within a bracket expression, the name of a character class enclosed in [: and : ] stands for the list of all characters belonging to that class. Standard character class names are: alnum, alpha, blank, cntrl, digit, graph, lower, print, punct, space, upper, xdigit. These stand for the character classes defined in ctype. A locale can provide others. A character class cannot be used as an endpoint of a range.

There are two special cases of bracket expressions: the bracket expressions [: < : ] and [: > : ] are constraints, matching empty strings at the beginning and end of a word respectively. A word is defined as a sequence of word characters that is neither preceded nor followed by word characters. A word character is an alnum character (as defined by ctype) or an underscore. This is an extension, compatible with but not specified by POSIX 1003.2, and should be used with caution in software intended to be portable to other systems. The constraint escapes described below are usually preferable (they are no more standard, but are certainly easier to type).

9.7.3.3. Regular Expression Escapes

Escapes are special sequences beginning with \ followed by an alphanumeric character. Escapes come in several varieties: character entry, class shorthands, constraint escapes, and back references. A \ followed by an alphanumeric character but not constituting a valid escape is illegal in AREs. In EREs, there are no escapes: outside a bracket expression, a \ followed by an alphanumeric character merely stands for that character as an ordinary character, and inside a bracket expression, \ is an ordinary character. (The latter is the one actual incompatibility between EREs and AREs.)

Character-entry escapes exist to make it easier to specify non-printing and otherwise inconvenient characters in REs. They are shown in Table 9-15.

Class-shorthand escapes provide shorthands for certain commonly-used character classes. They are shown in Table 9-16.
A *constraint escape* is a constraint, matching the empty string if specific conditions are met, written as an escape. They are shown in Table 9-17.

A *back reference* \( \text{\(n\)} \) matches the same string matched by the previous parenthesized subexpression specified by the number \( n \) (see Table 9-18). For example, \( ([bc]) \text{\(\backslash\)} \) matches \( bb \) or \( cc \) but not \( bc \) or \( cb \). The subexpression must entirely precede the back reference in the RE. Subexpressions are numbered in the order of their leading parentheses. Non-capturing parentheses do not define subexpressions.

**Note:** Keep in mind that an escape's leading \( \backslash \) will need to be doubled when entering the pattern as an SQL string constant. For example:

\[
'123' \sim E'^{\backslash d(3)}' \text{ true}
\]

**Table 9-15. Regular Expression Character-Entry Escapes**

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\a</td>
<td>alert (bell) character, as in C</td>
</tr>
<tr>
<td>\b</td>
<td>backspace, as in C</td>
</tr>
<tr>
<td>\B</td>
<td>synonym for \ to help reduce the need for backslash doubling</td>
</tr>
<tr>
<td>\cX</td>
<td>(where ( X ) is any character) the character whose low-order 5 bits are the same as those of ( X ), and whose other bits are all zero</td>
</tr>
<tr>
<td>\e</td>
<td>the character whose collating-sequence name is ( \text{ESC} ), or failing that, the character with octal value 033</td>
</tr>
<tr>
<td>\f</td>
<td>form feed, as in C</td>
</tr>
<tr>
<td>\n</td>
<td>newline, as in C</td>
</tr>
<tr>
<td>\r</td>
<td>carriage return, as in C</td>
</tr>
<tr>
<td>\t</td>
<td>horizontal tab, as in C</td>
</tr>
<tr>
<td>\uwxxyz</td>
<td>(where ( wxyz ) is exactly four hexadecimal digits) the UTF16 (Unicode, 16-bit) character ( \text{U+}wxyz ) in the local byte ordering</td>
</tr>
<tr>
<td>\Ustuvwxyz</td>
<td>(where ( stuvwxyz ) is exactly eight hexadecimal digits) reserved for a somewhat-hypothetical Unicode extension to 32 bits</td>
</tr>
<tr>
<td>\v</td>
<td>vertical tab, as in C</td>
</tr>
<tr>
<td>\xhhhh</td>
<td>(where ( hh ) is any sequence of hexadecimal digits) the character whose hexadecimal value is ( 0xhhh ) (a single character no matter how many hexadecimal digits are used)</td>
</tr>
<tr>
<td>\0</td>
<td>the character whose value is 0</td>
</tr>
<tr>
<td>\xy</td>
<td>(where ( xy ) is exactly two octal digits, and is not a back reference) the character whose octal value is ( 0xy )</td>
</tr>
</tbody>
</table>
Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\xyz</td>
<td>(where \xyz is exactly three octal digits, and is not a back reference) the character whose octal value is 0\xyz</td>
</tr>
</tbody>
</table>

Hexadecimal digits are 0-9, a-f, and A-F. Octal digits are 0-7.

The character-entry escapes are always taken as ordinary characters. For example, \135 is ] in ASCII, but \135 does not terminate a bracket expression.

Table 9-16. Regular Expression Class-Shorthand Escapes

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\d</td>
<td>[:digit:]</td>
</tr>
<tr>
<td>\s</td>
<td>[:space:]</td>
</tr>
<tr>
<td>\w</td>
<td>[:alnum:]_ (note underscore is included)</td>
</tr>
<tr>
<td>\D</td>
<td>[^[:digit:]]</td>
</tr>
<tr>
<td>\S</td>
<td>[^[:space:]]</td>
</tr>
<tr>
<td>\W</td>
<td>[^[:alnum:]_] (note underscore is included)</td>
</tr>
</tbody>
</table>

Within bracket expressions, \d, \s, and \w lose their outer brackets, and \D, \S, and \W are illegal. (So, for example, \[a-c\d] is equivalent to \[a-c][:digit:]. Also, \[a-c\D], which is equivalent to \[a-c^[[:digit:]], is illegal.)

Table 9-17. Regular Expression Constraint Escapes

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\A</td>
<td>matches only at the beginning of the string (see Section 9.7.3.5 for how this differs from ^)</td>
</tr>
<tr>
<td>\m</td>
<td>matches only at the beginning of a word</td>
</tr>
<tr>
<td>\M</td>
<td>matches only at the end of a word</td>
</tr>
<tr>
<td>\y</td>
<td>matches only at the beginning or end of a word</td>
</tr>
<tr>
<td>\Y</td>
<td>matches only at a point that is not the beginning or end of a word</td>
</tr>
<tr>
<td>\Z</td>
<td>matches only at the end of the string (see Section 9.7.3.5 for how this differs from $)</td>
</tr>
</tbody>
</table>

A word is defined as in the specification of [:<:] and [:>:] above. Constraint escapes are illegal within bracket expressions.

Table 9-18. Regular Expression Back References

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\m</td>
<td>(where \m is a nonzero digit) a back reference to the \m'th subexpression</td>
</tr>
</tbody>
</table>
Escape | Description
--- | ---
\mnn | (where \(m\) is a nonzero digit, and \(nn\) is some more digits, and the decimal value \(mnn\) is not greater than the number of closing capturing parentheses seen so far) a back reference to the \(mnn\)th subexpression

**Note:** There is an inherent historical ambiguity between octal character-entry escapes and back references, which is resolved by heuristics, as hinted at above. A leading zero always indicates an octal escape. A single non-zero digit, not followed by another digit, is always taken as a back reference. A multidigit sequence not starting with a zero is taken as a back reference if it comes after a suitable subexpression (i.e. the number is in the legal range for a back reference), and otherwise is taken as octal.

### 9.7.3.4. Regular Expression Metasyntax

In addition to the main syntax described above, there are some special forms and miscellaneous syntactic facilities available.

Normally the flavor of RE being used is determined by `regex_flavor`. However, this can be overridden by a `director` prefix. If an RE begins with `***`, the rest of the RE is taken as an ARE regardless of `regex_flavor`. If an RE begins with `***=`, the rest of the RE is taken to be a literal string, with all characters considered ordinary characters.

An ARE can begin with embedded options: a sequence `(xyz)` (where `xyz` is one or more alphabetic characters) specifies options affecting the rest of the RE. These options override any previously determined options (including both the RE flavor and case sensitivity). The available option letters are shown in Table 9-19.

**Table 9-19. ARE Embedded-Option Letters**

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>b</td>
<td>rest of RE is a BRE</td>
</tr>
<tr>
<td>c</td>
<td>case-sensitive matching (overrides operator type)</td>
</tr>
<tr>
<td>e</td>
<td>rest of RE is an ERE</td>
</tr>
<tr>
<td>i</td>
<td>case-insensitive matching (see Section 9.7.3.5) (overrides operator type)</td>
</tr>
<tr>
<td>m</td>
<td>historical synonym for n</td>
</tr>
<tr>
<td>n</td>
<td>newline-sensitive matching (see Section 9.7.3.5)</td>
</tr>
<tr>
<td>p</td>
<td>partial newline-sensitive matching (see Section 9.7.3.5)</td>
</tr>
<tr>
<td>q</td>
<td>rest of RE is a literal (&quot;quoted&quot;) string, all ordinary characters</td>
</tr>
<tr>
<td>s</td>
<td>non-newline-sensitive matching (default)</td>
</tr>
<tr>
<td>t</td>
<td>tight syntax (default; see below)</td>
</tr>
</tbody>
</table>
Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\w</td>
<td>inverse partial newline-sensitive (&quot;weird&quot;) matching (see Section 9.7.3.5)</td>
</tr>
<tr>
<td>\x</td>
<td>expanded syntax (see below)</td>
</tr>
</tbody>
</table>

Embedded options take effect at the ) terminating the sequence. They can appear only at the start of an ARE (after the ***: director if any).

In addition to the usual (right) RE syntax, in which all characters are significant, there is an expanded syntax, available by specifying the embedded \x option. In the expanded syntax, white-space characters in the RE are ignored, as are all characters between a # and the following newline (or the end of the RE). This permits paragraphing and commenting a complex RE. There are three exceptions to that basic rule:

- a white-space character or # preceded by \ is retained
- white space or # within a bracket expression is retained
- white space and comments cannot appear within multicharacter symbols, such as (?:

For this purpose, white-space characters are blank, tab, newline, and any character that belongs to the space character class.

Finally, in an ARE, outside bracket expressions, the sequence (?#ttt) (where ttt is any text not containing a ) is a comment, completely ignored. Again, this is not allowed between the characters of multicharacter symbols, like (?:. Such comments are more a historical artifact than a useful facility, and their use is deprecated; use the expanded syntax instead.

None of these metasyntax extensions is available if an initial ***= director has specified that the user’s input be treated as a literal string rather than as an RE.

9.7.3.5. Regular Expression Matching Rules

In the event that an RE could match more than one substring of a given string, the RE matches the one starting earliest in the string. If the RE could match more than one substring starting at that point, either the longest possible match or the shortest possible match will be taken, depending on whether the RE is greedy or non-greedy.

Whether an RE is greedy or not is determined by the following rules:

- Most atoms, and all constraints, have no greediness attribute (because they cannot match variable amounts of text anyway).
- Adding parentheses around an RE does not change its greediness.
- A quantified atom with a fixed-repetition quantifier (\{m\} or \{m\}? has the same greediness (possibly none) as the atom itself.
- A quantified atom with other normal quantifiers (including \{m, n\} with m equal to n) is greedy (prefers longest match).
- A quantified atom with a non-greedy quantifier (including \{m, n\}? with m equal to n) is non-greedy (prefers shortest match).
- A branch — that is, an RE that has no top-level | operator — has the same greediness as the first quantified atom in it that has a greediness attribute.
- An RE consisting of two or more branches connected by the | operator is always greedy.
The above rules associate greediness attributes not only with individual quantified atoms, but with branches and entire REs that contain quantified atoms. What that means is that the matching is done in such a way that the branch, or whole RE, matches the longest or shortest possible substring as a whole. Once the length of the entire match is determined, the part of it that matches any particular subexpression is determined on the basis of the greediness attribute of that subexpression, with subexpressions starting earlier in the RE taking priority over ones starting later.

An example of what this means:

```sql
SELECT SUBSTRING('XY1234Z', 'Y*([0-9]{1,3})');
Result: 123
```

```sql
SELECT SUBSTRING('XY1234Z', 'Y*?(0-9){1,3}');
Result: 1
```

In the first case, the RE as a whole is greedy because `Y*` is greedy. It can match beginning at the `Y`, and it matches the longest possible string starting there, i.e., `Y123`. The output is the parenthesized part of that, or `123`. In the second case, the RE as a whole is non-greedy because `Y*?` is non-greedy. It can match beginning at the `Y`, and it matches the shortest possible string starting there, i.e., `Y1`. The subexpression `[0-9]{1,3}` is greedy but it cannot change the decision as to the overall match length; so it is forced to match just `1`.

In short, when an RE contains both greedy and non-greedy subexpressions, the total match length is either as long as possible or as short as possible, according to the attribute assigned to the whole RE. The attributes assigned to the subexpressions only affect how much of that match they are allowed to "eat" relative to each other.

The quantifiers `{1,1}` and `{1,1}?` can be used to force greediness or non-greediness, respectively, on a subexpression or a whole RE.

Match lengths are measured in characters, not collating elements. An empty string is considered longer than no match at all. For example: `bb*` matches the three middle characters of `abbbc`; `(week|wee)(night|knights)` matches all ten characters of `weeknights`; when `(.*).*` is matched against `abc` the parenthesized subexpression matches all three characters; and when `(a*)*` is matched against `bc` both the whole RE and the parenthesized subexpression match an empty string.

If case-independent matching is specified, the effect is much as if all case distinctions had vanished from the alphabet. When an alphabetic that exists in multiple cases appears as an ordinary character outside a bracket expression, it is effectively transformed into a bracket expression containing both cases, e.g. `x` becomes `[xX]`. When it appears inside a bracket expression, all case counterparts of it are added to the bracket expression, e.g. `[x]` becomes `[xX]` and `[^x]` becomes `[^xX]`.

If newline-sensitive matching is specified, `^` and bracket expressions using `^` will never match the newline character (so that matches will never cross newlines unless the RE explicitly arranges it) and `^` and `$` will match the empty string after and before a newline respectively, in addition to matching at beginning and end of string respectively. But the ARE escapes `\A` and `\Z` continue to match beginning or end of string only.

If partial newline-sensitive matching is specified, this affects `.` and bracket expressions as with newline-sensitive matching, but not `^` and `$`.

If inverse partial newline-sensitive matching is specified, this affects `^` and `.` as with newline-sensitive matching, but not `^` and `$`. bracket expressions. This isn’t very useful but is provided for symmetry.
9.7.3.6. Limits and Compatibility

No particular limit is imposed on the length of REs in this implementation. However, programs intended to be highly portable should not employ REs longer than 256 bytes, as a POSIX-compliant implementation can refuse to accept such REs.

The only feature of AREs that is actually incompatible with POSIX EREs is that \ does not lose its special significance inside bracket expressions. All other ARE features use syntax which is illegal or has undefined or unspecified effects in POSIX EREs; the *** syntax of directors likewise is outside the POSIX syntax for both BREs and EREs.

Many of the ARE extensions are borrowed from Perl, but some have been changed to clean them up, and a few Perl extensions are not present. Incompatibilities of note include \b, \B, the lack of special treatment for a trailing newline, the addition of complemented bracket expressions to the things affected by newline-sensitive matching, the restrictions on parentheses and back references in lookahead constraints, and the longest/shortest-match (rather than first-match) matching semantics.

Two significant incompatibilities exist between AREs and the ERE syntax recognized by pre-7.4 releases of PostgreSQL:

- In AREs, \ followed by an alphanumeric character is either an escape or an error, while in previous releases, it was just another way of writing the alphanumeric. This should not be much of a problem because there was no reason to write such a sequence in earlier releases.
- In AREs, \ remains a special character within [ ], so a literal \ within a bracket expression must be written \ \ .

While these differences are unlikely to create a problem for most applications, you can avoid them if necessary by setting regex_flavor to extended.

9.7.3.7. Basic Regular Expressions

BREs differ from EREs in several respects. |, +, and ? are ordinary characters and there is no equivalent for their functionality. The delimiters for bounds are \{ and \}, with { and } by themselves ordinary characters. The parentheses for nested subexpressions are \ ( and \), with ( and ) by themselves ordinary characters. ^ is an ordinary character except at the beginning of the RE or the beginning of a parenthesized subexpression. $ is an ordinary character except at the end of the RE or the end of a parenthesized subexpression, and * is an ordinary character if it appears at the beginning of the RE or the beginning of a parenthesized subexpression (after a possible leading ^). Finally, single-digit back references are available, and \< and \> are synonyms for [[<:]] and [[>:]] respectively; no other escapes are available.

9.8. Data Type Formatting Functions

The PostgreSQL formatting functions provide a powerful set of tools for converting various data types (date/time, integer, floating point, numeric) to formatted strings and for converting from formatted strings to specific data types. Table 9-20 lists them. These functions all follow a common calling convention: the first argument is the value to be formatted and the second argument is a template that defines the output or input format.
The `to_timestamp` function can also take a single double precision argument to convert from Unix epoch to timestamp with time zone. (Integer Unix epochs are implicitly cast to double precision.)

### Table 9-20. Formatting Functions

<table>
<thead>

<tr>
<td><code>to_timestamp(double precision)</code></td>
<td>timestamp with time zone</td>
<td>convert UNIX epoch to time stamp</td>
<td><code>to_timestamp(200120400)</code></td>
</tr>
</tbody>
</table>

In an output template string (for `to_char`), there are certain patterns that are recognized and replaced with appropriately-formatted data from the value to be formatted. Any text that is not a template pattern is simply copied verbatim. Similarly, in an input template string (for anything but `to_char`), template patterns identify the parts of the input data string to be looked at and the values to be found there.

Table 9-21 shows the template patterns available for formatting date and time values.

### Table 9-21. Template Patterns for Date/Time Formatting

<table>
<thead>
<tr>
<th>Pattern</th>

</tr>
<tr>
<td>TZ</td>
<td>time-zone name (upercase)</td>
</tr>
<tr>
<td>tz</td>
<td>time-zone name (lowercase)</td>
</tr>
</tbody>
</table>

Certain modifiers can be applied to any template pattern to alter its behavior. For example, `FM` is the `Month` pattern with the `FM` modifier. Table 9-22 shows the modifier patterns for date/time formatting.

Table 9-22. Template Pattern Modifiers for Date/Time Formatting

<table>
<thead>
<tr>
<th>Modifier</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>FM prefix</td>
<td>fill mode (suppress padding blanks and zeroes)</td>
<td>FMMonth</td>
</tr>
<tr>
<td>TH suffix</td>
<td>uppercase ordinal number suffix</td>
<td>DDTH</td>
</tr>
<tr>
<td>th suffix</td>
<td>lowercase ordinal number suffix</td>
<td>DDth</td>
</tr>
<tr>
<td>FX prefix</td>
<td>fixed format global option (see usage notes)</td>
<td>FX Month DD Day</td>
</tr>
<tr>
<td>TM prefix</td>
<td>translation mode (print localized day and month names based on lc_messages)</td>
<td>TMMonth</td>
</tr>
<tr>
<td>SP suffix</td>
<td>spell mode (not yet implemented)</td>
<td>DDSP</td>
</tr>
</tbody>
</table>

Usage notes for date/time formatting:

- `FM` suppresses leading zeroes and trailing blanks that would otherwise be added to make the output of a pattern be fixed-width.
- `TM` does not include trailing blanks.
- `to_timestamp` and `to_date` skip multiple blank spaces in the input string if the `FX` option is not used. `FX` must be specified as the first item in the template. For example `to_timestamp('2000 JUN', 'YYYY MON')` is correct, but `to_timestamp('2000 JUN', 'FXYYYY MON')` returns an error, because `to_timestamp`
expects one space only.

- Ordinary text is allowed in `to_char` templates and will be output literally. You can put a substring in double quotes to force it to be interpreted as literal text even if it contains pattern key words. For example, in "Hello Year YYYY", the YYYY will be replaced by the year data, but the single Y in Year will not be.

- If you want to have a double quote in the output you must precede it with a backslash, for example E'"YYYY Month"'. (Two backslashes are necessary because the backslash already has a special meaning when using the escape string syntax.)

- The YYYY conversion from string to `timestamp` or `date` has a restriction if you use a year with more than 4 digits. You must use some non-digit character or template after YYYY, otherwise the year is always interpreted as 4 digits. For example (with the year 20000):

```sql
to_date('200001131', 'YYYYMMDD') will be interpreted as a 4-digit year; instead use a non-digit separator after the year, like to_date('20000-1131', 'YYYY-MMDD') or to_date('20000Nov31', 'YYYYMonDD').
```

- In conversions from string to `timestamp` or `date`, the CC field is ignored if there is a Y, YYYY or Y,YYY field. If CC is used with YY or Y then the year is computed as (CC-1)*100+YY.

- An ISO week date (as distinct from a Gregorian date) can be specified to `to_timestamp` and `to_date` in one of two ways:

  - Year, week and weekday, for example `to_date('2006-42-4', 'IYYY-IW-ID')` returns the date 2006-10-19. If you omit the weekday it is assumed to be 1 (Monday).
  
  - Year and day of year, for example `to_date('2006-291', 'IYYY-IDDD')` also returns 2006-10-19.

Attempting to construct a date using a mixture of ISO week and Gregorian date fields is nonsensical, and could yield unexpected results. In the context of an ISO year, the concept of a 'month' or 'day of month' has no meaning. In the context of a Gregorian year, the ISO week has no meaning. Users should take care to keep Gregorian and ISO date specifications separate.

- Millisecond (MS) and microsecond (US) values in a conversion from string to `timestamp` are used as part of the seconds after the decimal point. For example `to_timestamp('12:3', 'SS:MS')` is not 3 milliseconds, but 300, because the conversion counts it as 12 + 0.3 seconds. This means for the format SS:MS, the input values 12:3, 12:30, and 12:300 specify the same number of milliseconds. To get three milliseconds, one must use 12:003, which the conversion counts as 12 + 0.003 = 12.003 seconds.

  Here is a more complex example: `to_timestamp('15:12:02.020.001230', 'HH:MI:SS.MS.US')` is 15 hours, 12 minutes, and 2 seconds + 20 milliseconds + 1230 microseconds = 2.021230 seconds.

- `to_char(..., 'ID')`'s day of the week numbering matches the `extract(isodow from ...)` function, but `to_char(..., 'D')`'s does not match `extract(dow from ...)`'s day numbering.

- `to_char(interval)` formats HH and HH12 as hours in a single day, while HH24 can output hours exceeding a single day, e.g. >24.

Table 9-23 shows the template patterns available for formatting numeric values.

**Table 9-23. Template Patterns for Numeric Formatting**
<table>
<thead>
<tr>
<th>Pattern</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>9</td>
<td>value with the specified number of digits</td>
</tr>
<tr>
<td>0</td>
<td>value with leading zeros</td>
</tr>
<tr>
<td>. (period)</td>
<td>decimal point</td>
</tr>
<tr>
<td>, (comma)</td>
<td>group (thousand) separator</td>
</tr>
<tr>
<td>PR</td>
<td>negative value in angle brackets</td>
</tr>
<tr>
<td>S</td>
<td>sign anchored to number (uses locale)</td>
</tr>
<tr>
<td>L</td>
<td>currency symbol (uses locale)</td>
</tr>
<tr>
<td>D</td>
<td>decimal point (uses locale)</td>
</tr>
<tr>
<td>G</td>
<td>group separator (uses locale)</td>
</tr>
<tr>
<td>MI</td>
<td>minus sign in specified position (if number &lt; 0)</td>
</tr>
<tr>
<td>PL</td>
<td>plus sign in specified position (if number &gt; 0)</td>
</tr>
<tr>
<td>SG</td>
<td>plus/minus sign in specified position</td>
</tr>
<tr>
<td>RN</td>
<td>roman numeral (input between 1 and 3999)</td>
</tr>
<tr>
<td>TH or th</td>
<td>ordinal number suffix</td>
</tr>
<tr>
<td>V</td>
<td>shift specified number of digits (see notes)</td>
</tr>
<tr>
<td>EEEEE</td>
<td>scientific notation (not implemented yet)</td>
</tr>
</tbody>
</table>

Usage notes for numeric formatting:

- A sign formatted using `SG`, `PL`, or `MI` is not anchored to the number; for example, `to_char(-12, 'S9999')` produces `- 12'`, but `to_char(-12, 'MI9999')` produces `'- 12'`. The Oracle implementation does not allow the use of `MI` ahead of `9`, but rather requires that `9` precede `MI`.
- `9` results in a value with the same number of digits as there are `9`s. If a digit is not available it outputs a space.
- `TH` does not convert values less than zero and does not convert fractional numbers.
- `PL`, `SG`, and `TH` are PostgreSQL extensions.
- `V` effectively multiplies the input values by $10^n$, where $n$ is the number of digits following `V`. `to_char` does not support the use of `V` combined with a decimal point. (E.g., `99.9V99` is not allowed.)

Table 9-24 shows some examples of the use of the `to_char` function.

**Table 9-24. to_char Examples**

<table>
<thead>
<tr>
<th>Expression</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>to_char(current_timestamp, 'Day, DD HH24:MI:SS')</code></td>
<td>'Tuesday, 06 05:39:18'</td>
</tr>
<tr>
<td><code>to_char(current_timestamp, 'FMDay, FMDD HH12:MI:SS')</code></td>
<td>'Tuesday, 6 05:39:18'</td>
</tr>
<tr>
<td><code>to_char(-0.1, '99.99')</code></td>
<td>'- .10'</td>
</tr>
<tr>
<td><code>to_char(-0.1, 'FM9.99')</code></td>
<td>'- .1'</td>
</tr>
<tr>
<td><code>to_char(0.1, '0.9')</code></td>
<td>' 0.1'</td>
</tr>
</tbody>
</table>
9.9. Date/Time Functions and Operators

Table 9-26 shows the available functions for date/time value processing, with details appearing in the following subsections. Table 9-25 illustrates the behaviors of the basic arithmetic operators (+, *, etc.). For formatting functions, refer to Section 9.8. You should be familiar with the background information on date/time data types from Section 8.5.

All the functions and operators described below that take time or timestamp inputs actually come in two variants: one that takes time with time zone or timestamp with time zone, and one that takes time without time zone or timestamp without time zone. For brevity, these
variants are not shown separately. Also, the + and * operators come in commutative pairs (for example both date + integer and integer + date); we show only one of each such pair.

### Table 9-25. Date/Time Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>+</td>

<tr>
<td>to_char()</td>
<td>text</td>
<td>Current date and time (like clock_timestamp, but as a text string); see Section 9.9.4</td>
</tr>
</tbody>
</table>
In addition to these functions, the SQL `OVERLAPS` operator is supported:

\[
(\text{start1}, \text{end1}) \ \text{OVERLAPS} \ (\text{start2}, \text{end2})
\]
\[
(\text{start1}, \text{length1}) \ \text{OVERLAPS} \ (\text{start2}, \text{length2})
\]

This expression yields true when two time periods (defined by their endpoints) overlap, false when they do not overlap. The endpoints can be specified as pairs of dates, times, or time stamps; or as a date, time, or time stamp followed by an interval.

\[
\text{SELECT} \ (\text{DATE} \ '2001-02-16', \ \text{DATE} \ '2001-12-21') \ \text{OVERLAPS} \ (\text{DATE} \ '2001-10-30', \ \text{DATE} \ '2002-10-30');
\]
\[\text{Result: true}\]

\[
\text{SELECT} \ (\text{DATE} \ '2001-02-16', \ \text{INTERVAL} \ '100\ days') \ \text{OVERLAPS} \ (\text{DATE} \ '2001-10-30', \ \text{DATE} \ '2002-10-30');
\]
\[\text{Result: false}\]

When adding an `interval` value to (or subtracting an `interval` value from) a `timestamp` with `time zone` value, the days component advances (or decrements) the date of the `timestamp` with `time zone` by the indicated number of days. Across daylight saving time changes (with the session time zone set to a time zone that recognizes DST), this means `interval '1\ day'` does not necessarily equal `interval '24\ hours'`. For example, with the session time zone set to `CST7CDT`, `timestamp` with `time zone '2005-04-02 12:00-07' + interval '1\ day'` will produce `timestamp` with `time zone '2005-04-03 12:00-06'`, while adding `interval '24\ hours'` to the same initial `timestamp` with `time zone produces `timestamp` with `time zone '2005-04-03 13:00-06'`, as there is a change in daylight saving time at 2005-04-03 02:00 in time zone CST7CDT.

Note there can be ambiguity in the months returned by `age` because different months have a different number of days. PostgreSQL's approach uses the month from the earlier of the two dates when calculating partial months. For example, `age('2004-06-01', '2004-04-30')` uses April to yield 1 mon 1 day, while using May would yield 1 mon 2 days because May has 31 days, while April has only 30.

### 9.9.1. EXTRACT, date_part

\[
\text{EXTRACT}(\text{field FROM source})
\]

The `extract` function retrieves subfields such as year or hour from date/time values. `source` must be a value expression of type `timestamp`, `time`, or `interval`. (Expressions of type `date` will be cast to `timestamp` and can therefore be used as well.) `field` is an identifier or string that selects what field to extract from the source value. The `extract` function returns values of type `double precision`. The following are valid field names:

- `century`
  - The century
Chapter 9. Functions and Operators

SELECT EXTRACT(CENTURY FROM TIMESTAMP '2000-12-16 12:21:13');
Result: 20

SELECT EXTRACT(CENTURY FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 21

The first century starts at 0001-01-01 00:00:00 AD, although they did not know it at the time. This definition applies to all Gregorian calendar countries. There is no century number 0, you go from -1 to 1. If you disagree with this, please write your complaint to: Pope, Cathedral Saint-Peter of Roma, Vatican.

PostgreSQL releases before 8.0 did not follow the conventional numbering of centuries, but just returned the year field divided by 100.

day

The day (of the month) field (1 - 31)

SELECT EXTRACT(DAY FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 16

decade

The year field divided by 10

SELECT EXTRACT(DECADE FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 200

dow

The day of the week as Sunday(0) to Saturday(6)

SELECT EXTRACT(DOW FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 5

Note that extract’s day of the week numbering is different from that of the to_char(..., ’D’) function.

doy

The day of the year (1 - 365/366)

SELECT EXTRACT(DOY FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 47

epoch

For date and timestamp values, the number of seconds since 1970-01-01 00:00:00-00 (can be negative); for interval values, the total number of seconds in the interval

SELECT EXTRACT(EPOCH FROM TIMESTAMP WITH TIME ZONE '2001-02-16 20:38:40-08');
Result: 982384720

SELECT EXTRACT(EPOCH FROM INTERVAL '5 days 3 hours');
Result: 442800

Here is how you can convert an epoch value back to a time stamp:

SELECT TIMESTAM WITH TIME ZONE 'epoch' + 982384720 * INTERVAL '1 second';

hour

The hour field (0 - 23)

SELECT EXTRACT(HOUR FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 20
Chapter 9. Functions and Operators

isodow

The day of the week as Monday(1) to Sunday(7)

```sql
SELECT EXTRACT(ISODOW FROM TIMESTAMP '2001-02-18 20:38:40');
Result: 7
```

This is identical to dow except for Sunday. This matches the ISO 8601 day of the week numbering.

isoyear

The ISO 8601 year that the date falls in (not applicable to intervals).

```sql
SELECT EXTRACT(ISOYEAR FROM DATE '2006-01-01');
Result: 2005
```

```sql
SELECT EXTRACT(ISOYEAR FROM DATE '2006-01-02');
Result: 2006
```

Each ISO year begins with the Monday of the week containing the 4th of January, so in early January or late December the ISO year may be different from the Gregorian year. See the week field for more information.

This field is not available in PostgreSQL releases prior to 8.3.

microseconds

The seconds field, including fractional parts, multiplied by 1 000 000. Note that this includes full seconds.

```sql
SELECT EXTRACT(MICROSECONDS FROM TIME '17:12:28.5');
Result: 28500000
```

millennium

The millennium

```sql
SELECT EXTRACT(MILLENNIUM FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 3
```

Years in the 1900s are in the second millennium. The third millennium starts January 1, 2001.

PostgreSQL releases before 8.0 did not follow the conventional numbering of millennia, but just returned the year field divided by 1000.

milliseconds

The seconds field, including fractional parts, multiplied by 1000. Note that this includes full seconds.

```sql
SELECT EXTRACT(MILLISECOND FROM TIME '17:12:28.5');
Result: 28500
```

minute

The minutes field (0 - 59)

```sql
SELECT EXTRACT(MINUTE FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 38
```

month

For timestamp values, the number of the month within the year (1 - 12); for interval values the number of months, modulo 12 (0 - 11)

```sql
SELECT EXTRACT(MONTH FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 2
```

```sql
SELECT EXTRACT(MONTH FROM INTERVAL '2 years 3 months');
```
Chapter 9. Functions and Operators

Result: 3

SELECT EXTRACT(MONTH FROM INTERVAL '2 years 13 months');
Result: 1

quarter

The quarter of the year (1 - 4) that the day is in

SELECT EXTRACT(QUARTER FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 1

second

The seconds field, including fractional parts (0 - 59)

SELECT EXTRACT(SECOND FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 40

SELECT EXTRACT(SECOND FROM TIME '17:12:28.5');
Result: 28.5

timezone

The time zone offset from UTC, measured in seconds. Positive values correspond to time zones east of UTC, negative values to zones west of UTC.

timezone_hour

The hour component of the time zone offset

timezone_minute

The minute component of the time zone offset

week

The number of the week of the year that the day is in. By definition (ISO 8601), the first week of a year contains January 4 of that year. (The ISO-8601 week starts on Monday.) In other words, the first Thursday of a year is in week 1 of that year.

Because of this, it is possible for early January dates to be part of the 52nd or 53rd week of the previous year. For example, 2005-01-01 is part of the 53rd week of year 2004, and 2006-01-01 is part of the 52nd week of year 2005.

SELECT EXTRACT(WEEK FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 7

year

The year field. Keep in mind there is no 0 AD, so subtracting BC years from AD years should be done with care.

SELECT EXTRACT(YEAR FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 2001

The extract function is primarily intended for computational processing. For formatting date/time values for display, see Section 9.8.

The date_part function is modeled on the traditional Ingres equivalent to the SQL-standard function extract:

date_part('field', source)

60 if leap seconds are implemented by the operating system
Note that here the field parameter needs to be a string value, not a name. The valid field names for date_part are the same as for extract.

SELECT date_part('day', TIMESTAMP '2001-02-16 20:38:40');
Result: 16

SELECT date_part('hour', INTERVAL '4 hours 3 minutes');
Result: 4

9.9.2. date_trunc

The function date_trunc is conceptually similar to the trunc function for numbers.

date_trunc('field', source)

source is a value expression of type timestamp or interval. (Values of type date and time are cast automatically, to timestamp or interval respectively.) field selects to which precision to truncate the input value. The return value is of type timestamp or interval with all fields that are less significant than the selected one set to zero (or one, for day and month).

Valid values for field are:

milliseconds
seconds
minutes
hours
days
weeks
months
quarters
years
decades
centuries
millennia

Examples:

SELECT date_trunc('hour', TIMESTAMP '2001-02-16 20:38:40');
Result: 2001-02-16 20:00:00

SELECT date_trunc('year', TIMESTAMP '2001-02-16 20:38:40');
Result: 2001-01-01 00:00:00

9.9.3. AT TIME ZONE

The AT TIME ZONE construct allows conversions of time stamps to different time zones. Table 9-27 shows its variants.
Table 9-27. AT TIME ZONE Variants

<table>
<thead>
<tr>
<th>Expression</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>timestamp without time zone AT TIME ZONE zone</td>
<td>timestamp with time zone</td>
<td>Treat given time stamp without time zone as located in the specified time zone</td>
</tr>
<tr>
<td>timestamp with time zone AT TIME ZONE zone</td>
<td>timestamp without time zone zone</td>
<td>Convert given time stamp with time zone to the new time zone</td>
</tr>
<tr>
<td>time with time zone AT TIME ZONE zone</td>
<td>time with time zone</td>
<td>Convert given time with time zone to the new time zone</td>
</tr>
</tbody>
</table>

In these expressions, the desired time zone zone can be specified either as a text string (e.g., 'PST') or as an interval (e.g., INTERVAL '-08:00'). In the text case, a time zone name can be specified in any of the ways described in Section 8.5.3.

Examples (supposing that the local time zone is PST8PDT):

SELECT TIMESTAMP '2001-02-16 20:38:40' AT TIME ZONE 'MST';
Result: 2001-02-16 19:38:40-08

SELECT TIMESTAMP WITH TIME ZONE '2001-02-16 20:38:40-05' AT TIME ZONE 'MST';
Result: 2001-02-16 18:38:40

The first example takes a time stamp without time zone and interprets it as MST time (UTC-7), which is then converted to PST (UTC-8) for display. The second example takes a time stamp specified in EST (UTC-5) and converts it to local time in MST (UTC-7).

The function timezone(zone, timestamp) is equivalent to the SQL-conforming construct timestamp AT TIME ZONE zone.

9.9.4. Current Date/Time

PostgreSQL provides a number of functions that return values related to the current date and time. These SQL-standard functions all return values based on the start time of the current transaction:

CURRENT_DATE
CURRENT_TIME
CURRENT_TIMESTAMP
CURRENT_TIME(precision)
CURRENT_TIMESTAMP(precision)
LOCALTIME
LOCALTIMESTAMP
LOCALTIME(precision)
LOCALTIMESTAMP(precision)

CURRENT_TIME and CURRENT_TIMESTAMP deliver values with time zone; LOCALTIME and LOCALTIMESTAMP deliver values without time zone.

CURRENT_TIME, CURRENT_TIMESTAMP, LOCALTIME, and LOCALTIMESTAMP can optionally be given a precision parameter, which causes the result to be rounded to that many fractional digits in the seconds field. Without a precision parameter, the result is given to the full available precision.

Some examples:
SELECT CURRENT_TIME;
Result: 14:39:53.662522-05

SELECT CURRENT_DATE;
Result: 2001-12-23

SELECT CURRENT_TIMESTAMP;
Result: 2001-12-23 14:39:53.662522-05

SELECT CURRENT_TIMESTAMP (2);
Result: 2001-12-23 14:39:53.66-05

SELECT LOCALTIMESTAMP;
Result: 2001-12-23 14:39:53.662522

Since these functions return the start time of the current transaction, their values do not change during the transaction. This is considered a feature: the intent is to allow a single transaction to have a consistent notion of the “current” time, so that multiple modifications within the same transaction bear the same timestamp.

Note: Other database systems might advance these values more frequently.

PostgreSQL also provides functions that return the start time of the current statement, as well as the actual current time at the instant the function is called. The complete list of non-SQL-standard time functions is:

now()
transaction_timestamp()
statement_timestamp()
clock_timestamp()
timeofday()

now() is a traditional PostgreSQL equivalent to CURRENT_TIMESTAMP. transaction_timestamp() is likewise equivalent to CURRENT_TIMESTAMP, but is named to clearly reflect what it returns. statement_timestamp() returns the start time of the current statement (more specifically, the time of receipt of the latest command message from the client). statement_timestamp() and transaction_timestamp() return the same value during the first command of a transaction, but might differ during subsequent commands. clock_timestamp() returns the actual current time, and therefore its value changes even within a single SQL command. timeofday() is a historical PostgreSQL function. Like clock_timestamp(), it returns the actual current time, but as a formatted text string rather than a timestamp with time zone value.

All the date/time data types also accept the special literal value now to specify the current date and time (again, interpreted as the transaction start time). Thus, the following three all return the same result:

SELECT CURRENT_TIMESTAMP;
SELECT now();
SELECT TIMESTAMP 'now'; -- incorrect for use with DEFAULT
Tip: You do not want to use the third form when specifying a `DEFAULT` clause while creating a table. The system will convert now to a timestamp as soon as the constant is parsed, so that when the default value is needed, the time of the table creation would be used! The first two forms will not be evaluated until the default value is used, because they are function calls. Thus they will give the desired behavior of defaulting to the time of row insertion.

### 9.9.5. Delaying Execution

The following function is available to delay execution of the server process:

```sql
pg_sleep(seconds)
```

`pg_sleep` makes the current session’s process sleep until `seconds` seconds have elapsed. `seconds` is a value of type `double precision`, so fractional-second delays can be specified. For example:

```sql
SELECT pg_sleep(1.5);
```

**Note:** The effective resolution of the sleep interval is platform-specific; 0.01 seconds is a common value. The sleep delay will be at least as long as specified. It might be longer depending on factors such as server load.

### Warning

Make sure that your session does not hold more locks than necessary when calling `pg_sleep`. Otherwise other sessions might have to wait for your sleeping process, slowing down the entire system.

### 9.10. Enum Support Functions

For enum types (described in Section 8.7), there are several functions that allow cleaner programming without hard-coding particular values of an enum type. These are listed in Table 9-28. The examples assume an enum type created as:

```sql
CREATE TYPE rainbow AS ENUM ('red', 'orange', 'yellow', 'green', 'blue', 'purple');
```

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example</th>
<th>Example Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>enum_first(ayenum)</code></td>
<td>Returns the first value of the input enum type</td>
<td><code>enum_first(null::rainbow)</code></td>
<td></td>
</tr>
<tr>
<td><code>enum_last(ayenum)</code></td>
<td>Returns the last value of the input enum type</td>
<td><code>enum_last(null::rainbow)</code></td>
<td><code>purple</code></td>
</tr>
</tbody>
</table>
Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example</th>
<th>Example Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>enum_range(anyenum)</code></td>
<td>Returns all values of the input enum type in an ordered array</td>
<td><code>enum_range(null::rainbow)</code></td>
<td><code>{red,orange,yellow,green,blue,purple}</code></td>
</tr>
<tr>
<td><code>enum_range(anyenum, anyenum)</code></td>
<td>Returns the range between the two given enum values, as an ordered array. The values must be from the same enum type. If the first parameter is null, the result will start with the first value of the enum type. If the second parameter is null, the result will end with the last value of the enum type.</td>
<td><code>enum_range('orange'::rainbow, 'green'::rainbow)</code></td>
<td><code>{orange,yellow,green}</code></td>
</tr>
<tr>
<td></td>
<td></td>
<td><code>enum_range(NULL, 'green'::rainbow)</code></td>
<td><code>{red,orange,yellow,green}</code></td>
</tr>
<tr>
<td></td>
<td></td>
<td><code>enum_range('orange'::rainbow, NULL)</code></td>
<td><code>{orange,yellow,green,blue,purple}</code></td>
</tr>
</tbody>
</table>

Notice that except for the two-argument form of `enum_range`, these functions disregard the specific value passed to them; they care only about its declared data type. Either null or a specific value of the type can be passed, with the same result. It is more common to apply these functions to a table column or function argument than to a hardwired type name as suggested by the examples.

9.11. Geometric Functions and Operators

The geometric types `point`, `box`, `lseg`, `line`, `path`, `polygon`, and `circle` have a large set of native support functions and operators, shown in Table 9-29, Table 9-30, and Table 9-31.

### Caution

Note that the “same as” operator, `~=` represents the usual notion of equality for the `point`, `box`, `polygon`, and `circle` types. Some of these types also have an `=` operator, but `=` compares for equal areas only. The other scalar comparison operators (<, <= and so on) likewise compare areas for these types.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>+</td>
<td>Translation</td>
<td>box '((0,0),(1,1))' + point '(2.0,0)'</td>
</tr>
<tr>
<td>-</td>
<td>Translation</td>
<td>box '((0,0),(1,1))' - point '(2.0,0)'</td>
</tr>
<tr>
<td>*</td>
<td>Scaling/rotation</td>
<td>box '((0,0),(1,1))' * point '(2.0,0)'</td>
</tr>
<tr>
<td>/</td>
<td>Scaling/rotation</td>
<td>box '((0,0),(2,2))' / point '(2.0,0)'</td>
</tr>
</tbody>
</table>
### Chapter 9. Functions and Operators

<table>
<thead>
<tr>

</tbody>
</table>
Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>?-</td>
<td></td>
<td>Is perpendicular?</td>
</tr>
<tr>
<td>lseg '((0,0),(0,1))'</td>
<td></td>
<td>lseg '((-1,0),(1,0))'</td>
</tr>
<tr>
<td>?</td>
<td></td>
<td></td>
</tr>
<tr>
<td>@&gt;</td>
<td></td>
<td>Contains?</td>
</tr>
<tr>
<td>circle '((0,0),2)' @&gt; point '(1,1)'</td>
<td></td>
<td></td>
</tr>
<tr>
<td>&lt;@</td>
<td></td>
<td>Contained in or on?</td>
</tr>
<tr>
<td>point '(1,1)' &lt;@ circle '((0,0),2)'</td>
<td></td>
<td></td>
</tr>
<tr>
<td>~=</td>
<td></td>
<td>Same as?</td>
</tr>
<tr>
<td>polygon '((0,0),(1,1))' ~= polygon '((1,1),(0,0))'</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Note:** Before PostgreSQL 8.2, the containment operators @> and <@ were respectively called ~ and @. These names are still available, but are deprecated and will eventually be retired.

### Table 9-30. Geometric Functions

<table>
<thead>
<tr>

</tr>
<tr>
<td>circle)</td>
<td></td>
<td>polygon</td>
<td></td>
</tr>
<tr>
<td>polygon(path)</td>
<td>polygon</td>
<td>path to polygon</td>
<td>polygon(path '((0,0),(1,1),(2,2))')</td>
</tr>
</tbody>
</table>

It is possible to access the two component numbers of a point as though it were an array with indices 0 and 1. For example, if \( t.p \) is a point column then \( \text{SELECT } p[0] \text{ FROM } t \) retrieves the X coordinate and \( \text{UPDATE } t \text{ SET } p[1] = ... \) changes the Y coordinate. In the same way, a value of type box or lseg can be treated as an array of two point values.

The area function works for the types box, circle, and path. The area function only works on the path data type if the points in the path are non-intersecting. For example, the path \(((0,0),(0,1),(2,1),(2,2),(1,2),(1,0),(0,0))\)::PATH won’t work, however, the following visually identical path \(((0,0),(0,1),(1,1),(1,2),(2,2),(2,1),(1,1),(1,0),(0,0))\)::PATH will work. If the concept of an intersecting versus non-intersecting path is confusing, draw both of the above paths side by side on a piece of graph paper.

9.12. Network Address Functions and Operators

Table 9-32 shows the operators available for the cidr and inet types. The operators <<, <<<, >>, and >>> test for subnet inclusion. They consider only the network parts of the two addresses, ignoring any host part, and determine whether one network part is identical to or a subnet of the other.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;</td>
<td>is less than</td>
<td>inet ‘192.168.1.5’ &lt; inet ‘192.168.1.6’</td>
</tr>
<tr>
<td>&lt;=</td>
<td>is less than or equal</td>
<td>inet ‘192.168.1.5’ &lt;= inet ‘192.168.1.5’</td>
</tr>
<tr>
<td>=</td>
<td>equals</td>
<td>inet ‘192.168.1.5’ = inet ‘192.168.1.5’</td>
</tr>
<tr>
<td>&gt;=</td>
<td>is greater or equal</td>
<td>inet ‘192.168.1.5’ &gt;= inet ‘192.168.1.5’</td>
</tr>
<tr>
<td>&gt;</td>
<td>is greater than</td>
<td>inet ‘192.168.1.5’ &gt; inet ‘192.168.1.5’</td>
</tr>
<tr>
<td>&lt;&gt;</td>
<td>is not equal</td>
<td>inet ‘192.168.1.5’ &lt;&gt; inet ‘192.168.1.4’</td>
</tr>
<tr>
<td>&lt;&lt;</td>
<td>is contained within</td>
<td>inet ‘192.168.1.5’ &lt;&lt; inet ‘192.168.1/24’</td>
</tr>
</tbody>
</table>
Table 9-33 shows the functions available for use with the cidr and inet types. The host, text, and abbrev functions are primarily intended to offer alternative display formats.

### Table 9-33. cidr and inet Functions

<table>
<thead>
<tr>

<tr>
<td>hostmask(inet)</td>
<td>inet</td>
<td>construct host mask for network</td>
<td>hostmask('192.168.128/30')</td>
<td>192.168.128/30</td>
</tr>
<tr>
<td>masklen(inet)</td>
<td>int</td>
<td>extract netmask length</td>
<td>masklen('192.168.128/16')</td>
<td>24</td>
</tr>
<tr>
<td>netmask(inet)</td>
<td>inet</td>
<td>construct netmask for network</td>
<td>netmask('192.168.128/16')</td>
<td>192.168.128/24</td>
</tr>
<tr>
<td>network(inet)</td>
<td>cidr</td>
<td>extract network part of address</td>
<td>network('192.168.128/16')</td>
<td>192.168.128/16</td>
</tr>
<tr>
<td>set_masklen(inet)</td>
<td>inet</td>
<td>set netmask length for inet value</td>
<td>set_masklen('192.168.128/16')</td>
<td>24</td>
</tr>
</tbody>
</table>
Chapter 9. Functions and Operators

Table 9-34. Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Return Type</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>set_masklen</td>
<td>cidr</td>
<td>set netmask length for cidr value</td>
<td>set_masklen('129.26.68.0/16'::cidr, 16)</td>
<td></td>
</tr>
<tr>
<td>text</td>
<td>text</td>
<td>extract IP address and netmask</td>
<td>text(inet '192.168.1.5')</td>
<td>192.168.1.5/32</td>
</tr>
</tbody>
</table>

Any cidr value can be cast to inet implicitly or explicitly; therefore, the functions shown above as operating on inet also work on cidr values. (Where there are separate functions for inet and cidr, it is because the behavior should be different for the two cases.) Also, it is permitted to cast an inet value to cidr. When this is done, any bits to the right of the netmask are silently zeroed to create a valid cidr value. In addition, you can cast a text value to inet or cidr using normal casting syntax: for example, inet(expression) or colname::cidr.

Table 9-34 shows the functions available for use with the macaddr type. The function trunc(macaddr) returns a MAC address with the last 3 bytes set to zero. This can be used to associate the remaining prefix with a manufacturer.

Table 9-34. macaddr Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Return Type</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>trunc(macaddr)</td>
<td>macaddr</td>
<td>set last 3 bytes to zero</td>
<td>trunc(macaddr '12:34:56:78:90:ab')</td>
<td>12:34:56:00:00:00</td>
</tr>
</tbody>
</table>

The macaddr type also supports the standard relational operators (>, <, etc.) for lexicographical ordering.

9.13. Text Search Functions and Operators

Table 9-35, Table 9-36 and Table 9-37 summarize the functions and operators that are provided for full text searching. See Chapter 12 for a detailed explanation of PostgreSQL’s text search facility.

Table 9-35. Text Search Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>@@</td>
<td>tsvector matches tsquery ?</td>
<td>to_tsvector('fat cats ate rats') @@ to_tsquery('cat &amp; rat')</td>
<td>t</td>
</tr>
<tr>
<td>@@@</td>
<td>same as @@, but see Section 12.9</td>
<td>to_tsvector('fat cats ate rats') @@@ to_tsquery('cat &amp; rat')</td>
<td>t</td>
</tr>
</tbody>
</table>
### Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td>concatenate tsvector</td>
</tr>
<tr>
<td>&amp;&amp;</td>
<td>AND tsquery together</td>
<td>'fat</td>
<td>rat':tsquery &amp;&amp; 'cat':tsquery</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>OR tsquery together</td>
</tr>
<tr>
<td>!!!</td>
<td>negate tsquery</td>
<td>!! 'cat':tsquery</td>
<td>'cat'</td>
</tr>
<tr>
<td>@&gt;</td>
<td>tsquery contains another ?</td>
<td>'cat':tsquery @&gt; f</td>
<td>'cat &amp; rat':tsquery</td>
</tr>
<tr>
<td>@&lt;</td>
<td>tsquery is contained in ?</td>
<td>'cat':tsquery @&lt;</td>
<td>'cat &amp; rat':tsquery</td>
</tr>
</tbody>
</table>

**Note:** The tsquery containment operators consider only the lexemes listed in the two queries, ignoring the combining operators.

In addition to the operators shown in the table, the ordinary B-tree comparison operators (=, <, etc) are defined for types tsvector and tsquery. These are not very useful for text searching but allow, for example, unique indexes to be built on columns of these types.

### Table 9-36. Text Search Functions

</tr>
</tbody>
</table>
### Table 9-37. Text Search Debugging Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Return Type</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>ts_rewrite(query tsquery, select text)</td>
<td>tsquery</td>
<td>replace using targets and substitutes from a SELECT command</td>
<td><code>SELECT ts_rewrite('a &amp; b'::tsquery, 'SELECT t,s FROM aliases')</code></td>
<td>'b' &amp; ( 'foo'</td>
</tr>
<tr>
<td>get_current_ts_config()</td>
<td>regconfig</td>
<td>get default text search configuration</td>
<td><code>get_current_ts_config()</code></td>
<td></td>
</tr>
<tr>
<td>tsvector_update_trigger()</td>
<td>trigger</td>
<td>trigger function for automatic tsvector column update</td>
<td><code>CREATE TRIGGER ... tsvector_update_trigger(tsvcol, 'pg_catalog.swedish', title, body)</code></td>
<td></td>
</tr>
<tr>
<td>tsvector_update_trigger_column()</td>
<td>trigger</td>
<td>trigger function for automatic tsvector column update</td>
<td><code>CREATE TRIGGER ... tsvector_update_trigger_column(tsvcol, configcol, title, body)</code></td>
<td></td>
</tr>
</tbody>
</table>

**Note:** All the text search functions that accept an optional `regconfig` argument will use the configuration specified by `default_text_search_config` when that argument is omitted.

The functions in Table 9-37 are listed separately because they are not usually used in everyday text searching operations. They are helpful for development and debugging of new text search configurations.

</tr>
</tbody>
</table>

### 9.14. XML Functions

The functions and function-like expressions described in this section operate on values of type xml. Check Section 8.13 for information about the xml type. The function-like expressions `xmlparse` and `xmlserialize` for converting to and from type xml are not repeated here. Use of many of these functions requires the installation to have been built with `configure --with-libxml`. 
9.14.1. Producing XML Content

A set of functions and function-like expressions are available for producing XML content from SQL data. As such, they are particularly suitable for formatting query results into XML documents for processing in client applications.

9.14.1.1. xmlcomment

xmlcomment(text)

The function xmlcomment creates an XML value containing an XML comment with the specified text as content. The text cannot contain -- or end with a - so that the resulting construct is a valid XML comment. If the argument is null, the result is null.

Example:

```sql
SELECT xmlcomment('hello');
```

xmlcomment
------------------
<!--hello-->

9.14.1.2. xmlconcat

xmlconcat(xml[, ...])

The function xmlconcat concatenates a list of individual XML values to create a single value containing an XML content fragment. Null values are omitted; the result is only null if there are no nonnull arguments.

Example:

```sql
SELECT xmlconcat('<abc/>', '<bar>foo</bar>');
```

xmlconcat
------------------
<abc/><bar>foo</bar>

XML declarations, if present, are combined as follows. If all argument values have the same XML version declaration, that version is used in the result, else no version is used. If all argument values have the standalone declaration value "yes", then that value is used in the result. If all argument values have a standalone declaration value and at least one is "no", then that is used in the result. Else the result will have no standalone declaration. If the result is determined to require a standalone declaration but no version declaration, a version declaration with version 1.0 will be used because XML requires an XML declaration to contain a version declaration. Encoding declarations are ignored and removed in all cases.

Example:

```sql
SELECT xmlconcat('<?xml version="1.1"?><foo/>', '<?xml version="1.1" standalone="no"?><bar/>');
```
9.14.1.3. `xmlelement`  

`xmlelement(name name [, xmlattributes(value [AS attname] [, ... ])] [, content, ...])`

The `xmlelement` expression produces an XML element with the given name, attributes, and content. Examples:

```
SELECT xmlelement(name foo);

xmlelement
----------
<foo/>
```

```
SELECT xmlelement(name foo, xmlattributes('xyz' as bar));

xmlelement
----------
<foo bar="xyz"/>
```

```
SELECT xmlelement(name foo, xmlattributes(current_date as bar), 'cont', 'ent');

xmlelement
----------
<foo bar="2007-01-26">content</foo>
```

Element and attribute names that are not valid XML names are escaped by replacing the offending characters by the sequence `_xHHHH_`, where `HHHH` is the character’s Unicode codepoint in hexadecimal notation. For example:

```
SELECT xmlelement(name "foo$bar", xmlattributes('xyz' as "a&b"));

xmlelement
----------
<foo_x0024_bar a_x0026_b="xyz"/>
```

An explicit attribute name need not be specified if the attribute value is a column reference, in which case the column’s name will be used as attribute name by default. In any other case, the attribute must be given an explicit name. So this example is valid:

```
CREATE TABLE test (a xml, b xml);
SELECT xmlelement(name test, xmlattributes(a, b)) FROM test;
```

But these are not:

```
SELECT xmlelement(name test, xmlattributes('constant'), a, b) FROM test;
SELECT xmlelement(name test, xmlattributes(func(a, b))) FROM test;
```
Element content, if specified, will be formatted according to data type. If the content is itself of type xml, complex XML documents can be constructed. For example:

```sql
SELECT xmlelement(name foo, xmlattributes('xyz' as bar),
    xmlelement(name abc),
    xmlcomment('test'),
    xmlelement(name xyz));
```

```
xmlelement----------------------------------------------
<foo bar="xyz"><abc/><!--test-->xyz></foo>
```

Content of other types will be formatted into valid XML character data. This means in particular that the characters `<`, `>`, and `&` will be converted to entities. Binary data (data type `bytea`) will be represented in base64 or hex encoding, depending on the setting of the configuration parameter `xmlbinary`. The particular behavior for individual data types is expected to evolve in order to align the SQL and PostgreSQL data types with the XML Schema specification, at which point a more precise description will appear.

### 9.14.1.4. `xmlforest`

```sql
xmlforest(content [AS name] [, ...])
```

The `xmlforest` expression produces an XML forest (sequence) of elements using the given names and content.

Examples:

```sql
SELECT xmlforest('abc' AS foo, 123 AS bar);
```

```
xmlelement-------------------------------
<foo>abc</foo><bar>123</bar>
```

```sql
SELECT xmlforest(table_name, column_name) FROM information_schema.columns WHERE table_schema = 'pg_catalog';
```

```
xmlelement-------------------------------------------------------------------------------------------
<table_name>pg_authid</table_name><column_name>rolname</column_name>
<table_name>pg_authid</table_name><column_name>rolsuper</column_name>
...```

As seen in the second example, the element name can be omitted if the content value is a column reference, in which case the column name is used by default. Otherwise, a name must be specified. Element names that are not valid XML names are escaped as shown for `xmlelement` above. Similarly, content data is escaped to make valid XML content, unless it is already of type `xml`.

Note that XML forests are not valid XML documents if they consist of more than one element. So it might be useful to wrap `xmlforest` expressions in `xmlelement`.

195
9.14.1.5. xmlpi

xmlpi(name target [, content])

The xmlpi expression creates an XML processing instruction. The content, if present, must not contain the character sequence ?>

Example:

SELECT xmlpi(name php, 'echo "hello world";');

xmlpi
----------------------------
<?php echo "hello world";?>

9.14.1.6. xmlroot

xmlroot(xml, version text|no value [, standalone yes|no|no value])

The xmlroot expression alters the properties of the root node of an XML value. If a version is specified, this replaces the value in the version declaration, if a standalone value is specified, this replaces the value in the standalone declaration.

SELECT xmlroot(xmlparse(document '<?xml version="1.1"?><content>abc</content>'), version '1.0', standalone yes);

xmlroot
----------------------------------------
<?xml version="1.0" standalone="yes"?><content>abc</content>

9.14.1.7. xmlagg

xmlagg(xml)

The function xmlagg is, unlike the other functions described here, an aggregate function. It concatenates the input values to the aggregate function call, like xmlconcat does. See Section 9.18 for general information about aggregate functions.

Example:

CREATE TABLE test (y int, x xml);
INSERT INTO test VALUES (1, '<foo>abc</foo>');
INSERT INTO test VALUES (2, '<bar/>');
SELECT xmlagg(x) FROM test;
xmlagg
----------------------
<foo>abc</foo><bar/>
Note that in the current implementation, the order of the concatenation is in principle undefined. Making the input values to be sorted in some other way will usually work, however. For instance, in the above example, one could influence the order like so:

```sql
SELECT xmlagg(x) FROM (SELECT * FROM test ORDER BY y DESC) AS tab;
```

```
xmlagg
----------------------
<bar/><foo>abc</foo>
```

But this approach is not guaranteed to work in all situations and in all versions of PostgreSQL. A future version of PostgreSQL will probably provide an additional feature to control the order in a proper way (`xmlagg(expr ORDER BY expr, expr, ...`).

### 9.14.1.8. XML Predicates

**xml** IS DOCUMENT

The expression **IS DOCUMENT** returns true if the argument XML value is a proper XML document, false if it is not (that is, it is a content fragment), or null if the argument is null. See Section 8.13 about the difference between documents and content fragments.

### 9.14.2. Processing XML

To process values of data type **xml**, PostgreSQL offers the function **xpath**, which evaluates XPath 1.0 expressions.

```sql
xpath(xpath, xml[, nsarray])
```

The function **xpath** evaluates the XPath expression **xpath** against the XML value **xml**. It returns an array of XML values corresponding to the node set produced by the XPath expression.

The third argument of the function is an array of namespace mappings. This array should be a two-dimensional array with the length of the second axis being equal to 2 (i.e., it should be an array of arrays, each of which consists of exactly 2 elements). The first element of each array entry is the namespace name, the second the namespace URI.

Example:

```sql
```

```
xpath
--------
{test}
(1 row)
```
Chapter 9. Functions and Operators

9.14.3. Mapping Tables to XML

The following functions map the contents of relational tables to XML values. They can be thought of as XML export functionality.

```sql
table_to_xml(tbl regclass, nulls boolean, tableforest boolean, targetns text)
query_to_xml(query text, nulls boolean, tableforest boolean, targetns text)
cursor_to_xml(cursor refcursor, count int, nulls boolean, tableforest boolean, targetns text)
```

The return type of each function is `xml`.

- `table_to_xml` maps the content of the named table, passed as parameter `tbl`. The `regclass` type accepts strings identifying tables using the usual notation, including optional schema qualifications and double quotes. `query_to_xml` executes the query whose text is passed as parameter `query` and maps the result set. `cursor_to_xml` fetches the indicated number of rows from the cursor specified by the parameter `cursor`. This variant is recommendable if large tables have to be mapped, because the result value is built up in memory by each function.

If `tableforest` is false, then the resulting XML document looks like this:

```xml
<tablename>
  <row>
    <columnname1 data</columnname1>
    <columnname2 data</columnname2>
  </row>
  ...
</tablename>
```

If `tableforest` is true, the result is an XML content fragment that looks like this:

```xml
<tablename>
  <columnname1 data</columnname1>
  <columnname2 data</columnname2>
</tablename>
<tablename>
  ...
</tablename>
<tablename>
  ...
</tablename>
```

If no table name is available, that is, when mapping a query or a cursor, the string `table` is used in the first format, `row` in the second format.

The choice between these formats is up to the user. The first format is a proper XML document, which will be important in many applications. The second format tends to be more useful in the `cursor_to_xml` function if the result values are to be reassembled into one document later on. The functions for producing XML content discussed above, in particular `xmlelement`, can be used to alter the results to taste.

The data values are mapped in the same way as described for the function `xmlelement` above.

The parameter `nulls` determines whether null values should be included in the output. If true, null values in columns are represented as
where xsi is the XML namespace prefix for XML Schema Instance. An appropriate namespace declaration will be added to the result value. If false, columns containing null values are simply omitted from the output.

The parameter targetns specifies the desired XML namespace of the result. If no particular namespace is wanted, an empty string should be passed.

The following functions return XML Schema documents describing the mappings made by the data mappings produced by the corresponding functions above.

```sql
table_to_xmlschema(tbl regclass, nulls boolean, tableforest boolean, targetns text)
query_to_xmlschema(query text, nulls boolean, tableforest boolean, targetns text)
cursor_to_xmlschema(cursor refcursor, nulls boolean, tableforest boolean, targetns text)
```

It is essential that the same parameters are passed in order to obtain matching XML data mappings and XML Schema documents.

The following functions produce XML data mappings and the corresponding XML Schema in one document (or forest), linked together. They can be useful where self-contained and self-describing results are wanted.

```sql
table_to_xml_and_xmlschema(tbl regclass, nulls boolean, tableforest boolean, targetns text)
query_to_xml_and_xmlschema(query text, nulls boolean, tableforest boolean, targetns text)
```

In addition, the following functions are available to produce analogous mappings of entire schemas or the entire current database.

```sql
schema_to_xml(schema name, nulls boolean, tableforest boolean, targetns text)
schema_to_xmlschema(schema name, nulls boolean, tableforest boolean, targetns text)
schema_to_xml_and_xmlschema(schema name, nulls boolean, tableforest boolean, targetns text)
```

```sql
database_to_xml(nulls boolean, tableforest boolean, targetns text)
database_to_xmlschema(nulls boolean, tableforest boolean, targetns text)
database_to_xml_and_xmlschema(nulls boolean, tableforest boolean, targetns text)
```

Note that these potentially produce a lot of data, which needs to be built up in memory. When requesting content mappings of large schemas or databases, it may be worthwhile to consider mapping the tables separately instead, possibly even through a cursor.

The result of a schema content mapping looks like this:

```xml
<schemaname>
  table1-mapping
  table2-mapping
  ...
</schemaname>
```

where the format of a table mapping depends on the tableforest parameter as explained above.

The result of a database content mapping looks like this:

```xml
<dbname>
</dbname>
```
where the schema mapping is as above.

As an example for using the output produced by these functions, Figure 9-1 shows an XSLT stylesheet that converts the output of `table_to_xml_and_xmlschema` to an HTML document containing a tabular rendition of the table data. In a similar manner, the result data of these functions can be converted into other XML-based formats.

**Figure 9-1. XSLT stylesheet for converting SQL/XML output to HTML**

```xml
<?xml version="1.0"?>
<xsl:stylesheet version="1.0"
    xmlns:xsl="http://www.w3.org/1999/XSL/Transform"
    xmlns:xsd="http://www.w3.org/2001/XMLSchema"
    xmlns="http://www.w3.org/1999/xhtml">
    <xsl:output method="xml"
        doctype-system="http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd"
        doctype-public="-//W3C/DTD XHTML 1.0 Strict//EN"
        indent="yes"/>
    <xsl:template match="/">
        <html>
            <head>
                <title><xsl:value-of select="name(current())"></title>
            </head>
            <body>
                <table>
                    <tr>
                        <xsl:for-each select="$schema/xsd:complexType[@name=$tabletypename]/xsd:sequence/xsd:element/@name">
                            <th><xsl:value-of select="."/></th>
                        </xsl:for-each>
                    </tr>
                    <xsl:for-each select="row">
                        <tr>
                            <xsl:for-each select="*">
                                <td><xsl:value-of select="."/></td>
                            </xsl:for-each>
                        </tr>
                    </xsl:for-each>
                </table>
            </body>
        </html>
    </xsl:template>
</xsl:stylesheet>
```
9.15. Sequence Manipulation Functions

This section describes PostgreSQL’s functions for operating on sequence objects. Sequence objects (also called sequence generators or just sequences) are special single-row tables created with CREATE SEQUENCE. A sequence object is usually used to generate unique identifiers for rows of a table. The sequence functions, listed in Table 9-38, provide simple, multiuser-safe methods for obtaining successive sequence values from sequence objects.

Table 9-38. Sequence Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>currval(regclass)</td>
<td>bigint</td>
<td>Return value most recently obtained with nextval for specified sequence</td>
</tr>
<tr>
<td>lastval()</td>
<td>bigint</td>
<td>Return value most recently obtained with nextval for any sequence</td>
</tr>
<tr>
<td>nextval(regclass)</td>
<td>bigint</td>
<td>Advance sequence and return new value</td>
</tr>
<tr>
<td>setval(regclass, bigint)</td>

<td>Set sequence’s current value</td>
</tr>
<tr>
<td>setval(regclass, bigint, boolean)</td>
<td>bigint</td>
<td>Set sequence’s current value and is_called flag</td>
</tr>
</tbody>
</table>

The sequence to be operated on by a sequence-function call is specified by a regclass argument, which is just the OID of the sequence in the pg_class system catalog. You do not have to look up the OID by hand, however, since the regclass data type’s input converter will do the work for you. Just write the sequence name enclosed in single quotes, so that it looks like a literal constant. To achieve some compatibility with the handling of ordinary SQL names, the string will be converted to lowercase unless it contains double quotes around the sequence name. Thus:

nextval(‘foo’) operates on sequence foo
nextval(‘FOO’) operates on sequence foo
nextval(‘"Foo“’) operates on sequence Foo

The sequence name can be schema-qualified if necessary:

nextval(‘myschema.foo’) operates on myschema.foo
nextval(‘"myschema".foo’) same as above
nextval(‘foo’) searches search path for foo
See Section 8.16 for more information about regclass.

**Note:** Before PostgreSQL 8.1, the arguments of the sequence functions were of type text, not regclass, and the above-described conversion from a text string to an OID value would happen at run time during each call. For backwards compatibility, this facility still exists, but internally it is now handled as an implicit coercion from text to regclass before the function is invoked.

When you write the argument of a sequence function as an unadorned literal string, it becomes a constant of type regclass. Since this is really just an OID, it will track the originally identified sequence despite later renaming, schema reassignment, etc. This “early binding” behavior is usually desirable for sequence references in column defaults and views. But sometimes you will want “late binding” where the sequence reference is resolved at run time. To get late-binding behavior, force the constant to be stored as a text constant instead of regclass:

```
nextval('foo'::text)  foo is looked up at runtime
```

Note that late binding was the only behavior supported in PostgreSQL releases before 8.1, so you might need to do this to preserve the semantics of old applications.

Of course, the argument of a sequence function can be an expression as well as a constant. If it is a text expression then the implicit coercion will result in a run-time lookup.

The available sequence functions are:

- **nextval**
  
  Advance the sequence object to its next value and return that value. This is done atomically: even if multiple sessions execute `nextval` concurrently, each will safely receive a distinct sequence value.

- **currval**
  
  Return the value most recently obtained by `nextval` for this sequence in the current session. (An error is reported if `nextval` has never been called for this sequence in this session.) Notice that because this is returning a session-local value, it gives a predictable answer whether or not other sessions have executed `nextval` since the current session did.

- **lastval**
  
  Return the value most recently returned by `nextval` in the current session. This function is identical to `currval`, except that instead of taking the sequence name as an argument it fetches the value of the last sequence that `nextval` was used on in the current session. It is an error to call `lastval` if `nextval` has not yet been called in the current session.

- **setval**
  
  Reset the sequence object’s counter value. The two-parameter form sets the sequence’s `last_value` field to the specified value and sets its `is_called` field to true, meaning that the next `nextval` will advance the sequence before returning a value. The value reported by `currval` is also set to the specified value. In the three-parameter form, `is_called` can be set either true or false. true has the same effect as the two-parameter form. If it’s set to false, the next `nextval` will return exactly the specified value, and sequence advancement commences with the following `nextval`. Furthermore, the value reported by `currval` is not changed in this case (this is a change from pre-8.3 behavior). For example,

```
SELECT setval('foo', 42);  Next nextval will return 43
SELECT setval('foo', 42, true);  Same as above
SELECT setval('foo', 42, false);  Next nextval will return 42
```
The result returned by `setval` is just the value of its second argument.

If a sequence object has been created with default parameters, `nextval` calls on it will return successive values beginning with 1. Other behaviors can be obtained by using special parameters in the `CREATE SEQUENCE` command; see its command reference page for more information.

**Important:** To avoid blocking of concurrent transactions that obtain numbers from the same sequence, a `nextval` operation is never rolled back; that is, once a value has been fetched it is considered used, even if the transaction that did the `nextval` later aborts. This means that aborted transactions might leave unused “holes” in the sequence of assigned values. `setval` operations are never rolled back, either.

### 9.16. Conditional Expressions

This section describes the SQL-compliant conditional expressions available in PostgreSQL.

**Tip:** If your needs go beyond the capabilities of these conditional expressions you might want to consider writing a stored procedure in a more expressive programming language.

#### 9.16.1. CASE

The SQL `CASE` expression is a generic conditional expression, similar to if/else statements in other languages:

```
CASE WHEN condition THEN result
    [WHEN ...]
    [ELSE result]
END
```

CASE clauses can be used wherever an expression is valid. `condition` is an expression that returns a boolean result. If the result is true then the value of the `CASE` expression is the `result` that follows the condition. If the result is false any subsequent `WHEN` clauses are searched in the same manner. If no `WHEN condition` is true then the value of the case expression is the `result` in the `ELSE` clause. If the `ELSE` clause is omitted and no condition matches, the result is null.

An example:

```
SELECT * FROM test;
```

```
a
---
1
2
3
```

```
SELECT a,
    CASE WHEN a=1 THEN 'one'
         WHEN a=2 THEN 'two'
```

203
The data types of all the result expressions must be convertible to a single output type. See Section 10.5 for more detail.

The following “simple” CASE expression is a specialized variant of the general form above:

```
CASE  expression
  WHEN  value  THEN  result
  [WHEN  ...]
  [ELSE  result]
END
```

The expression is computed and compared to all the value specifications in the WHEN clauses until one is found that is equal. If no match is found, the result in the ELSE clause (or a null value) is returned. This is similar to the switch statement in C.

The example above can be written using the simple CASE syntax:

```
SELECT a,
    CASE a WHEN 1 THEN 'one'
           WHEN 2 THEN 'two'
           ELSE 'other'
    END
FROM test;
```

A CASE expression does not evaluate any subexpressions that are not needed to determine the result. For example, this is a possible way of avoiding a division-by-zero failure:

```
SELECT ... WHERE CASE WHEN x <> 0 THEN y/x > 1.5 ELSE false END;
```

\section{COALESCE}

\texttt{COALESCE(value [, ...])}
The **COALESCE** function returns the first of its arguments that is not null. Null is returned only if all arguments are null. It is often used to substitute a default value for null values when data is retrieved for display, for example:

```
SELECT COALESCE(description, short_description, '(none)') ...
```

Like a **CASE** expression, **COALESCE** will not evaluate arguments that are not needed to determine the result; that is, arguments to the right of the first non-null argument are not evaluated. This SQL-standard function provides capabilities similar to **NVL** and **IFNULL**, which are used in some other database systems.

### 9.16.3. NULLIF

**NULLIF**(value1, value2)

The **NULLIF** function returns a null value if value1 and value2 are equal; otherwise it returns value1. This can be used to perform the inverse operation of the **COALESCE** example given above:

```
SELECT NULLIF(value, '(none)') ...
```

If value1 is (none), return a null, otherwise return value1.

### 9.16.4. GREATEST and LEAST

**GREATEST**(value [, ...])

**LEAST**(value [, ...])

The **GREATEST** and **LEAST** functions select the largest or smallest value from a list of any number of expressions. The expressions must all be convertible to a common data type, which will be the type of the result (see Section 10.5 for details). NULL values in the list are ignored. The result will be NULL only if all the expressions evaluate to NULL.

Note that **GREATEST** and **LEAST** are not in the SQL standard, but are a common extension. Some other databases make them return NULL if any argument is NULL, rather than only when all are NULL.

### 9.17. Array Functions and Operators

Table 9-39 shows the operators available for array types.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>-</code></td>
<td>equal</td>
<td>ARRAY[1.1,2.1,3.1] == int[] = ARRAY[1,2,3]</td>
<td></td>
</tr>
</tbody>
</table>
Array comparisons compare the array contents element-by-element, using the default B-Tree comparison function for the element data type. In multidimensional arrays the elements are visited in row-major order (last subscript varies most rapidly). If the contents of two arrays are equal but the dimensionality is different, the first difference in the dimensionality information determines the sort order. (This is a change from versions of PostgreSQL prior to 8.2: older versions would claim that two arrays with the same contents were equal, even if the number of dimensions or subscript ranges were different.)

See Section 8.14 for more details about array operator behavior.

Table 9-40 shows the functions available for use with array types. See Section 8.14 for more discussion and examples of the use of these functions.

Table 9-40. array Functions

<td></td>
<td>array-to-element concatenation</td>
</tr>
</tbody>
</table>
### 9.18. Aggregate Functions

**Aggregate functions** compute a single result value from a set of input values. The built-in aggregate functions are listed in Table 9-41 and Table 9-42. The special syntax considerations for aggregate functions are explained in Section 4.2.7. Consult Section 2.7 for additional introductory information.

#### Table 9-41. General-Purpose Aggregate Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Argument Type</th>
<th>Return Type</th>
<th>Description</th>
<th>Example</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>avg(expression)</td>
<td>smallint, int, bigint, real,</td>
<td>numeric</td>
<td>the average (arithmetic mean) of all input values</td>
<td>avg(10, 20, 30)</td>
<td>20</td>
</tr>
<tr>
<td></td>
<td>double precision, numeric, or</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>interval</td>
<td></td>

</tr>
<tr>
<td>bit_and(expression)</td>
<td>smallint, bigint, or bit</td>
<td>same as</td>
<td>the bitwise AND of all non-null input values, or null if none</td>
<td>bit_and(10, 20, 30)</td>
<td>10</td>
</tr>
<tr>
<td>bit_or(expression)</td>
<td>smallint, bigint, or bit</td>
<td>same as</td>
<td>the bitwise OR of all non-null input values, or null if none</td>
<td>bit_or(10, 20, 30)</td>
<td>11</td>
</tr>
</tbody>
</table>
### Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Argument Type</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>bool_and(expression)</code></td>
<td><code>bool</code></td>
<td><code>bool</code></td>
<td>true if all input values are true, otherwise false</td>
</tr>
<tr>
<td><code>bool_or(expression)</code></td>
<td><code>bool</code></td>
<td><code>bool</code></td>
<td>true if at least one input value is true, otherwise false</td>
</tr>
<tr>
<td><code>count(*)</code></td>
<td></td>
<td><code>bigint</code></td>
<td>number of input rows</td>
</tr>
<tr>
<td><code>count(expression)</code></td>
<td>any</td>
<td><code>bigint</code></td>
<td>number of input rows for which the value of <code>expression</code> is not null</td>
</tr>
<tr>
<td><code>every(expression)</code></td>
<td><code>bool</code></td>
<td><code>bool</code></td>
<td>equivalent to <code>bool_and</code></td>
</tr>
<tr>
<td><code>max(expression)</code></td>
<td>any array, numeric,</td>
<td><code>same as</code></td>
<td>maximum value of <code>expression</code> across all input values</td>
</tr>
<tr>
<td></td>
<td>string, or date/time type</td>
<td>argument type</td>
<td></td>
</tr>
<tr>
<td><code>min(expression)</code></td>
<td>any array, numeric,</td>
<td><code>same as</code></td>
<td>minimum value of <code>expression</code> across all input values</td>
</tr>
<tr>
<td></td>
<td>string, or date/time type</td>
<td>argument type</td>
<td></td>
</tr>
<tr>
<td><code>sum(expression)</code></td>
<td><code>smallint</code>, <code>int</code>,</td>
<td><code>bigint</code></td>
<td>sum of <code>expression</code> across all input values</td>
</tr>
<tr>
<td></td>
<td><code>bigint</code>, <code>real</code>,</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>double precision</code>,</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>numeric</code>, <code>or</code></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>interval</code></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

It should be noted that except for `count`, these functions return a null value when no rows are selected. In particular, `sum` of no rows returns null, not zero as one might expect. The `coalesce` function can be used to substitute zero for null when necessary.

**Note:** Boolean aggregates `bool_and` and `bool_or` correspond to standard SQL aggregates `every` and `any` or `some`. As for `any` and `some`, it seems that there is an ambiguity built into the standard syntax:

```sql
SELECT b1 = ANY(SELECT b2 FROM t2 ...)) FROM t1 ...
```

Here `ANY` can be considered both as leading to a subquery or as an aggregate if the select expression returns 1 row. Thus the standard name cannot be given to these aggregates.

**Note:** Users accustomed to working with other SQL database management systems might be surprised by the performance of the `count` aggregate when it is applied to the entire table. A query like:

```sql
SELECT count(*) FROM sometable;
```

will be executed by PostgreSQL using a sequential scan of the entire table.
Table 9-42 shows aggregate functions typically used in statistical analysis. (These are separated out merely to avoid cluttering the listing of more-commonly-used aggregates.) Where the description mentions \( N \), it means the number of input rows for which all the input expressions are non-null. In all cases, null is returned if the computation is meaningless, for example when \( N \) is zero.

### Table 9-42. Aggregate Functions for Statistics

<table>
<thead>
<tr>

<td>double precision</td>
<td>(\text{sum}(Y^2) - \text{sum}(Y)^2/N) (&quot;sum of squares&quot; of the dependent variable)</td>
</tr>
</tbody>
</table>
9.19. Subquery Expressions

This section describes the SQL-compliant subquery expressions available in PostgreSQL. All of the expression forms documented in this section return Boolean (true/false) results.

9.19.1. EXISTS

 EXISTS (subquery)

The argument of EXISTS is an arbitrary SELECT statement, or subquery. The subquery is evaluated to determine whether it returns any rows. If it returns at least one row, the result of EXISTS is “true”; if the subquery returns no rows, the result of EXISTS is “false”.

The subquery can refer to variables from the surrounding query, which will act as constants during any one evaluation of the subquery.

The subquery will generally only be executed far enough to determine whether at least one row is returned, not all the way to completion. It is unwise to write a subquery that has any side effects (such as calling sequence functions); whether the side effects occur or not might be difficult to predict.

Since the result depends only on whether any rows are returned, and not on the contents of those rows, the output list of the subquery is normally uninteresting. A common coding convention is to write all EXISTS tests in the form EXISTS(SELECT 1 WHERE ...). There are exceptions to this rule however, such as subqueries that use INTERSECT.
This simple example is like an inner join on `col2`, but it produces at most one output row for each `tab1` row, even if there are multiple matching `tab2` rows:

```sql
SELECT col1 FROM tab1 WHERE EXISTS(SELECT 1 FROM tab2 WHERE col2 = tab1.col2);
```

### 9.19.2. **IN**

`expression IN (subquery)`

The right-hand side is a parenthesized subquery, which must return exactly one column. The left-hand expression is evaluated and compared to each row of the subquery result. The result of **IN** is “true” if any equal subquery row is found. The result is “false” if no equal row is found (including the special case where the subquery returns no rows).

Note that if the left-hand expression yields null, or if there are no equal right-hand values and at least one right-hand row yields null, the result of the **IN** construct will be null, not false. This is in accordance with SQL’s normal rules for Boolean combinations of null values.

As with **EXISTS**, it’s unwise to assume that the subquery will be evaluated completely.

```sql
row_constructor IN (subquery)
```

The left-hand side of this form of **IN** is a row constructor, as described in Section 4.2.11. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. The left-hand expressions are evaluated and compared row-wise to each row of the subquery result. The result of **IN** is “true” if any equal subquery row is found. The result is “false” if no equal row is found (including the special case where the subquery returns no rows).

As usual, null values in the rows are combined per the normal rules of SQL Boolean expressions. Two rows are considered equal if all their corresponding members are non-null and equal; the rows are unequal if any corresponding members are non-null and unequal; otherwise the result of that row comparison is unknown (null). If all the per-row results are either unequal or null, with at least one null, then the result of **IN** is null.

### 9.19.3. **NOT IN**

`expression NOT IN (subquery)`

The right-hand side is a parenthesized subquery, which must return exactly one column. The left-hand expression is evaluated and compared to each row of the subquery result. The result of **NOT IN** is “true” if only unequal subquery rows are found (including the special case where the subquery returns no rows). The result is “false” if any equal row is found.

Note that if the left-hand expression yields null, or if there are no equal right-hand values and at least one right-hand row yields null, the result of the **NOT IN** construct will be null, not true. This is in accordance with SQL’s normal rules for Boolean combinations of null values.

As with **EXISTS**, it’s unwise to assume that the subquery will be evaluated completely.

```sql
row_constructor NOT IN (subquery)
```
Chapter 9. Functions and Operators

The left-hand side of this form of \texttt{NOT IN} is a row constructor, as described in Section 4.2.11. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. The left-hand expressions are evaluated and compared row-wise to each row of the subquery result. The result of \texttt{NOT IN} is “true” if only unequal subquery rows are found (including the special case where the subquery returns no rows). The result is “false” if any equal row is found.

As usual, null values in the rows are combined per the normal rules of SQL Boolean expressions. Two rows are considered equal if all their corresponding members are non-null and equal; the rows are unequal if any corresponding members are non-null and unequal; otherwise the result of that row comparison is unknown (null). If all the per-row results are either unequal or null, with at least one null, then the result of \texttt{NOT IN} is null.

9.19.4. \texttt{ANY}/\texttt{SOME}

\begin{verbatim}
expression operator ANY (subquery)
expression operator SOME (subquery)
\end{verbatim}

The right-hand side is a parenthesized subquery, which must return exactly one column. The left-hand expression is evaluated and compared to each row of the subquery result using the given \texttt{operator}, which must yield a Boolean result. The result of \texttt{ANY} is “true” if any true result is obtained. The result is “false” if no true result is found (including the special case where the subquery returns no rows). \texttt{SOME} is a synonym for \texttt{ANY}. \texttt{IN} is equivalent to \texttt{= ANY}.

Note that if there are no successes and at least one right-hand row yields null for the operator’s result, the result of the \texttt{ANY} construct will be null, not false. This is in accordance with SQL’s normal rules for Boolean combinations of null values.

As with \texttt{EXISTS}, it’s unwise to assume that the subquery will be evaluated completely.

\begin{verbatim}
row_constructor operator ANY (subquery)
row_constructor operator SOME (subquery)
\end{verbatim}

The left-hand side of this form of \texttt{ANY} is a row constructor, as described in Section 4.2.11. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. The left-hand expressions are evaluated and compared row-wise to each row of the subquery result, using the given \texttt{operator}. The result of \texttt{ANY} is “true” if the comparison returns true for any subquery row. The result is “false” if the comparison returns false for every subquery row (including the special case where the subquery returns no rows). The result is NULL if the comparison does not return true for any row, and it returns NULL for at least one row.

See Section 9.20.5 for details about the meaning of a row-wise comparison.

9.19.5. \texttt{ALL}

\begin{verbatim}
expression operator ALL (subquery)
\end{verbatim}

The right-hand side is a parenthesized subquery, which must return exactly one column. The left-hand expression is evaluated and compared to each row of the subquery result using the given \texttt{operator}, which must yield a Boolean result. The result of \texttt{ALL} is “true” if all rows yield true (including the special case where the subquery returns no rows). The result is “false” if any false result is found. The result is NULL if the comparison does not return false for any row, and it returns NULL for at least one row.
Chapter 9. Functions and Operators

**NOT IN** is equivalent to `<>` **ALL**.

As with **EXISTS**, it’s unwise to assume that the subquery will be evaluated completely.

```
row_constructor operator ALL (subquery)
```

The left-hand side of this form of **ALL** is a row constructor, as described in Section 4.2.11. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. The left-hand expressions are evaluated and compared row-wise to each row of the subquery result, using the given **operator**. The result of **ALL** is “true” if the comparison returns true for all subquery rows (including the special case where the subquery returns no rows). The result is “false” if the comparison returns false for any subquery row. The result is NULL if the comparison does not return false for any subquery row, and it returns NULL for at least one row.

See Section 9.20.5 for details about the meaning of a row-wise comparison.

### 9.19.6. Row-wise Comparison

```
row_constructor operator (subquery)
```

The left-hand side is a row constructor, as described in Section 4.2.11. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. Furthermore, the subquery cannot return more than one row. (If it returns zero rows, the result is taken to be null.) The left-hand side is evaluated and compared row-wise to the single subquery result row.

See Section 9.20.5 for details about the meaning of a row-wise comparison.

### 9.20. Row and Array Comparisons

This section describes several specialized constructs for making multiple comparisons between groups of values. These forms are syntactically related to the subquery forms of the previous section, but do not involve subqueries. The forms involving array subexpressions are PostgreSQL extensions; the rest are SQL-compliant. All of the expression forms documented in this section return Boolean (true/false) results.

#### 9.20.1. IN

```
expression IN (value [, ...])
```

The right-hand side is a parenthesized list of scalar expressions. The result is “true” if the left-hand expression’s result is equal to any of the right-hand expressions. This is a shorthand notation for

```
expression = value1
OR
expression = value2
OR
...
```
Note that if the left-hand expression yields null, or if there are no equal right-hand values and at least one right-hand expression yields null, the result of the IN construct will be null, not false. This is in accordance with SQL’s normal rules for Boolean combinations of null values.

### 9.20.2. NOT IN

```sql
expression NOT IN (value [, ...])
```

The right-hand side is a parenthesized list of scalar expressions. The result is “true” if the left-hand expression’s result is unequal to all of the right-hand expressions. This is a shorthand notation for

```sql
expression <> value1 
AND 
expression <> value2 
AND 
...
```

Note that if the left-hand expression yields null, or if there are no equal right-hand values and at least one right-hand expression yields null, the result of the NOT IN construct will be null, not true as one might naively expect. This is in accordance with SQL’s normal rules for Boolean combinations of null values.

**Tip:** \( x \ NOT \ IN \ y \) is equivalent to \( NOT \ (x \ IN \ y) \) in all cases. However, null values are much more likely to trip up the novice when working with NOT IN than when working with IN. It’s best to express your condition positively if possible.

### 9.20.3. ANY/SOME (array)

```sql
expression operator ANY (array expression) 
expression operator SOME (array expression) 
```

The right-hand side is a parenthesized expression, which must yield an array value. The left-hand expression is evaluated and compared to each element of the array using the given operator, which must yield a Boolean result. The result of ANY is “true” if any true result is obtained. The result is “false” if no true result is found (including the special case where the array has zero elements).

If the array expression yields a null array, the result of ANY will be null. If the left-hand expression yields null, the result of ANY is ordinarily null (though a non-strict comparison operator could possibly yield a different result). Also, if the right-hand array contains any null elements and no true comparison result is obtained, the result of ANY will be null, not false (again, assuming a strict comparison operator). This is in accordance with SQL’s normal rules for Boolean combinations of null values.

SOME is a synonym for ANY.

### 9.20.4. ALL (array)

```sql
expression operator ALL (array expression) 
```
The right-hand side is a parenthesized expression, which must yield an array value. The left-hand expression is evaluated and compared to each element of the array using the given operator, which must yield a Boolean result. The result of \texttt{ALL} is "true" if all comparisons yield true (including the special case where the array has zero elements). The result is "false" if any false result is found.

If the array expression yields a null array, the result of \texttt{ALL} will be null. If the left-hand expression yields null, the result of \texttt{ALL} is ordinarily null (though a non-strict comparison operator could possibly yield a different result). Also, if the right-hand array contains any null elements and no false comparison result is obtained, the result of \texttt{ALL} will be null, not true (again, assuming a strict comparison operator). This is in accordance with SQL’s normal rules for Boolean combinations of null values.

\section*{9.20.5. Row-wise Comparison}

Each side is a row constructor, as described in Section 4.2.11. The two row values must have the same number of fields. Each side is evaluated and they are compared row-wise. Row comparisons are allowed when the operator is \texttt{=}, \texttt{<>}, \texttt{<}, \texttt{<=}, \texttt{>}, or \texttt{>=}, or has semantics similar to one of these. (To be specific, an operator can be a row comparison operator if it is a member of a B-Tree operator class, or is the negator of the \texttt{=} member of a B-Tree operator class.)

The \texttt{=} and \texttt{<>} cases work slightly differently from the others. Two rows are considered equal if all their corresponding members are non-null and equal; the rows are unequal if any corresponding members are non-null and unequal; otherwise the result of the row comparison is unknown (null).

For the \texttt{<}, \texttt{<}, \texttt{=}, \texttt{>}, and \texttt{>=} cases, the row elements are compared left-to-right, stopping as soon as an unequal or null pair of elements is found. If either of this pair of elements is null, the result of the row comparison is unknown (null); otherwise comparison of this pair of elements determines the result. For example, \texttt{ROW(1,2,NULL) < ROW(1,3,0)} yields true, not null, because the third pair of elements are not considered.

\textbf{Note:} Prior to PostgreSQL 8.2, the \texttt{<}, \texttt{<}, \texttt{>}, and \texttt{>=} cases were not handled per SQL specification. A comparison like \texttt{ROW(a,b) < ROW(c,d)} was implemented as \texttt{a < c AND b < d} whereas the correct behavior is equivalent to \texttt{a < c OR (a = c AND b < d)}.

\texttt{row_constructor IS DISTINCT FROM row_constructor}

This construct is similar to a \texttt{<>} row comparison, but it does not yield null for null inputs. Instead, any null value is considered unequal to (distinct from) any non-null value, and any two nulls are considered equal (not distinct). Thus the result will always be either true or false, never null.

\texttt{row_constructor IS NOT DISTINCT FROM row_constructor}

This construct is similar to a \texttt{=} row comparison, but it does not yield null for null inputs. Instead, any null value is considered unequal to (distinct from) any non-null value, and any two nulls are considered equal (not distinct). Thus the result will always be either true or false, never null.
9.21. Set Returning Functions

This section describes functions that possibly return more than one row. Currently the only functions in this class are series generating functions, as detailed in Table 9-43.

Table 9-43. Series Generating Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Argument Type</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>generate_series(start, stop)</td>
<td>int or bigint</td>
<td>setof int or setof bigint (same as argument type)</td>
<td>Generate a series of values, from start to stop with a step size of one</td>
</tr>
<tr>
<td>generate_series(start, stop, step)</td>
<td>int or bigint</td>
<td>setof int or setof bigint (same as argument type)</td>
<td>Generate a series of values, from start to stop with a step size of step</td>
</tr>
</tbody>
</table>

When step is positive, zero rows are returned if start is greater than stop. Conversely, when step is negative, zero rows are returned if start is less than stop. Zero rows are also returned for NULL inputs. It is an error for step to be zero. Some examples follow:

```sql
select * from generate_series(2,4);
generate_series
---
2
3
4
(3 rows)

select * from generate_series(5,1,-2);
generate_series
---
5
3
1
(3 rows)

select * from generate_series(4,3);
generate_series
---
(0 rows)

select current_date + s.a as dates from generate_series(0,14,7) as s(a);
dates
---
2004-02-05
2004-02-12
2004-02-19
(3 rows)
```
9.22. System Information Functions

Table 9-44 shows several functions that extract session and system information.

In addition to the functions listed in this section, there are a number of functions related to the statistics system that also provide system information. See Section 26.2.2 for more information.

Table 9-44. Session Information Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>current_database()</td>
<td>name</td>
<td>name of current database</td>
</tr>
<tr>
<td>current_schema()</td>
<td>name</td>
<td>name of current schema</td>
</tr>
<tr>
<td>current_schemas(boolean)</td>
<td>name[]</td>
<td>names of schemas in search path optionally including implicit schemas</td>
</tr>
<tr>
<td>current_user</td>
<td>name</td>
<td>user name of current execution context</td>
</tr>
<tr>
<td>inet_client_addr()</td>
<td>inet</td>
<td>address of the remote connection</td>
</tr>
<tr>
<td>inet_client_port()</td>
<td>int</td>
<td>port of the remote connection</td>
</tr>
<tr>
<td>inet_server_addr()</td>
<td>inet</td>
<td>address of the local connection</td>
</tr>
<tr>
<td>inet_server_port()</td>
<td>int</td>
<td>port of the local connection</td>
</tr>
<tr>
<td>pg_my_temp_schema()</td>
<td>oid</td>
<td>OID of session’s temporary schema, or 0 if none</td>
</tr>
<tr>
<td>pg_is_other_temp_schema(oid)</td>
<td>boolean</td>
<td>is schema another session’s temporary schema?</td>
</tr>
<tr>
<td>pg_postmaster_start_time()</td>
<td>timestamp with time zone</td>
<td>server start time</td>
</tr>
<tr>
<td>session_user</td>
<td>name</td>
<td>session user name</td>
</tr>
<tr>
<td>user</td>
<td>name</td>
<td>equivalent to current_user</td>
</tr>
<tr>
<td>version()</td>
<td>text</td>
<td>PostgreSQL version information</td>
</tr>
</tbody>
</table>

The `session_user` is normally the user who initiated the current database connection; but superusers can change this setting with `SET SESSION AUTHORIZATION`. The `current_user` is the user identifier that is applicable for permission checking. Normally, it is equal to the session user, but it can be changed with `SET ROLE`. It also changes during the execution of functions with the attribute `SECURITY DEFINER`. In Unix parlance, the session user is the “real user” and the current user is the “effective user”.

**Note:** `current_user`, `session_user`, and `user` have special syntactic status in SQL: they must be called without trailing parentheses.

current_schema returns the name of the schema that is at the front of the search path (or a null value if the search path is empty). This is the schema that will be used for any tables or other named objects that are created without specifying a target schema. current_schemas(boolean) returns an array of the names of all schemas presently in the search path. The Boolean option determines whether or not implicitly included system schemas such as `pg_catalog` are included in the search path returned.
Chapter 9. Functions and Operators

**Note:** The search path can be altered at run time. The command is:

```
SET search_path TO schema [, schema, ...]
```

inet_client_addr returns the IP address of the current client, and inet_client_port returns the port number. inet_server_addr returns the IP address on which the server accepted the current connection, and inet_server_port returns the port number. All these functions return NULL if the current connection is via a Unix-domain socket.

pg_my_temp_schema returns the OID of the current session’s temporary schema, or 0 if it has none (because it has not created any temporary tables). pg_is_other_temp_schema returns true if the given OID is the OID of any other session’s temporary schema. (This can be useful, for example, to exclude other sessions’ temporary tables from a catalog display.)

pg_postmaster_start_time returns the timestamp with time zone when the server started. version returns a string describing the PostgreSQL server’s version.

Table 9-45 lists functions that allow the user to query object access privileges programmatically. See Section 5.6 for more information about privileges.

### Table 9-45. Access Privilege Inquiry Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>has_database_privilege(user,</td>
<td>boolean</td>
<td>does user have privilege for database</td>
</tr>
<tr>
<td>database, privilege)</td>
<td></td>

</tr>
<tr>
<td>has_database_privilege(database)</td>
<td>boolean</td>
<td>does current user have privilege for database</td>
</tr>
<tr>
<td>has_function_privilege(user,</td>
<td>boolean</td>
<td>does user have privilege for function</td>
</tr>
<tr>
<td>function, privilege)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>has_function_privilege(function)</td>
<td>boolean</td>
<td>does current user have privilege for function</td>
</tr>
<tr>
<td>has_language_privilege(user,</td>
<td>boolean</td>
<td>does user have privilege for language</td>
</tr>
<tr>
<td>language, privilege)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>has_language_privilege(language)</td>
<td>boolean</td>
<td>does current user have privilege for language</td>
</tr>
<tr>
<td>has_schema_privilege(user,</td>
<td>boolean</td>
<td>does user have privilege for schema</td>
</tr>
<tr>
<td>schema, privilege)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>has_schema_privilege(schema,</td>
<td>boolean</td>
<td>does current user have privilege for schema</td>
</tr>
<tr>
<td>privilege)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>has_table_privilege(user,</td>
<td>boolean</td>
<td>does user have privilege for table</td>
</tr>
<tr>
<td>table, privilege)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>has_table_privilege(table,</td>
<td>boolean</td>
<td>does current user have privilege for table</td>
</tr>
<tr>
<td>privilege)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>has_tablespace_privilege(user,</td>
<td>boolean</td>
<td>does user have privilege for tablespace</td>
</tr>
<tr>
<td>tablespace, privilege)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>has_tablespace_privilege(tablespace, privilege)</td>
<td>boolean</td>
<td>does current user have privilege for tablespace</td>
</tr>
</tbody>
</table>
Chapter 9. Functions and Operators

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_has_role(user, role, privilege)</code></td>
<td>boolean</td>
<td>does user have privilege for role</td>
</tr>
<tr>
<td><code>pg_has_role(role, privilege)</code></td>
<td>boolean</td>
<td>does current user have privilege for role</td>
</tr>
</tbody>
</table>

**has_database_privilege** checks whether a user can access a database in a particular way. The possibilities for its arguments are analogous to **has_table_privilege**. The desired access privilege type must evaluate to **CREATE**, **CONNECT**, **TEMPORARY**, or **TEMP** (which is equivalent to **TEMPORARY**).

**has_function_privilege** checks whether a user can access a function in a particular way. The possibilities for its arguments are analogous to **has_table_privilege**. When specifying a function by a text string rather than by OID, the allowed input is the same as for the **regprocedure** data type (see Section 8.16). The desired access privilege type must evaluate to **EXECUTE**. An example is:

```sql
SELECT has_function_privilege('joeuser', 'myfunc(int, text)', 'execute');
```

**has_language_privilege** checks whether a user can access a procedural language in a particular way. The possibilities for its arguments are analogous to **has_table_privilege**. The desired access privilege type must evaluate to **USAGE**.

**has_schema_privilege** checks whether a user can access a schema in a particular way. The possibilities for its arguments are analogous to **has_table_privilege**. The desired access privilege type must evaluate to **CREATE** or **USAGE**.

**has_table_privilege** checks whether a user can access a table in a particular way. The user can be specified by name or by OID (**pg_authid.oid**), or if the argument is omitted **current_user** is assumed. The table can be specified by name or by OID. (Thus, there are actually six variants of **has_table_privilege**, which can be distinguished by the number and types of their arguments.) When specifying by name, the name can be schema-qualified if necessary. The desired access privilege type is specified by a text string, which must evaluate to one of the values **SELECT**, **INSERT**, **UPDATE**, **DELETE**, **REFERENCES**, or **TRIGGER**. (Case of the string is not significant, however.) An example is:

```sql
SELECT has_table_privilege('myschema.mytable', 'select');
```

**has_tablespace_privilege** checks whether a user can access a tablespace in a particular way. The possibilities for its arguments are analogous to **has_table_privilege**. The desired access privilege type must evaluate to **CREATE**.

**pg_has_role** checks whether a user can access a role in a particular way. The possibilities for its arguments are analogous to **has_table_privilege**. The desired access privilege type must evaluate to **MEMBER** or **USAGE**. **MEMBER** denotes direct or indirect membership in the role (that is, the right to do **SET ROLE**), while **USAGE** denotes whether the privileges of the role are immediately available without doing **SET ROLE**.

To test whether a user holds a grant option on the privilege, append **WITH GRANT OPTION** to the privilege key word; for example **'UPDATE WITH GRANT OPTION'**.

Table 9-46 shows functions that determine whether a certain object is **visible** in the current schema search path. For example, a table is said to be visible if its containing schema is in the search path and no table of the same name appears earlier in the search path. This is equivalent to the statement
that the table can be referenced by name without explicit schema qualification. To list the names of all visible tables:

```sql
SELECT relname FROM pg_class WHERE pg_table_is_visible(oid);
```

**Table 9-46. Schema Visibility Inquiry Functions**

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_conversion_is_visible(function_oid)</td>
<td>boolean</td>
<td>is conversion visible in search path</td>
</tr>
<tr>
<td>pg_function_is_visible(function_oid)</td>
<td>boolean</td>
<td>is function visible in search path</td>
</tr>
<tr>
<td>pg_operator_is_visible(operator_oid)</td>
<td>boolean</td>
<td>is operator visible in search path</td>
</tr>
<tr>
<td>pg_opclass_is_visible(opclass_oid)</td>
<td>boolean</td>
<td>is operator class visible in search path</td>
</tr>
<tr>
<td>pg_table_is_visible(table_oid)</td>
<td>boolean</td>
<td>is table visible in search path</td>
</tr>
<tr>
<td>pg_ts_config_is_visible(config_oid)</td>
<td>boolean</td>
<td>is text search configuration visible in search path</td>
</tr>
<tr>
<td>pg_ts_dict_is_visible(dict_oid)</td>
<td>boolean</td>
<td>is text search dictionary visible in search path</td>
</tr>
<tr>
<td>pg_ts_parser_is_visible(parser_oid)</td>
<td>boolean</td>
<td>is text search parser visible in search path</td>
</tr>
<tr>
<td>pg_ts_template_is_visible(template_oid)</td>
<td>boolean</td>
<td>is text search template visible in search path</td>
</tr>
<tr>
<td>pg_type_is_visible(type_oid)</td>
<td>boolean</td>
<td>is type (or domain) visible in search path</td>
</tr>
</tbody>
</table>

Each function performs the visibility check for one type of database object. Note that `pg_table_is_visible` can also be used with views, indexes and sequences; `pg_type_is_visible` can also be used with domains. For functions and operators, an object in the search path is visible if there is no object of the same name and argument data type(s) earlier in the path. For operator classes, both name and associated index access method are considered.

All these functions require object OIDs to identify the object to be checked. If you want to test an object by name, it is convenient to use the OID alias types (`regclass`, `regtype`, `regprocedure`, `regoperator`, `regconfig`, or `regdictionary`), for example:

```sql
SELECT pg_type_is_visible('myschema.widget'::regtype);
```

Note that it would not make much sense to test an unqualified name in this way — if the name can be recognized at all, it must be visible.

Table 9-47 lists functions that extract information from the system catalogs.

**Table 9-47. System Catalog Information Functions**

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
</table>

220
<table>
<thead>
<tr>
<th>Name</th>

<td>get underlying SELECT command for view</td>
</tr>
<tr>
<td><code>pg_tablespace_databases(tablespace_oid)</code></td>
<td>setof oid</td>
<td>get the set of database OIDs that have objects in the tablescape</td>
</tr>
</tbody>
</table>

`format_type` returns the SQL name of a data type that is identified by its type OID and possibly a
type modifier. Pass NULL for the type modifier if no specific modifier is known.

pg_get_constraintdef, pg_get_indexdef, pg_get_ruledef, and pg_get_triggerdef, respectively reconstruct the creating command for a constraint, index, rule, or trigger. (Note that this is a decompiled reconstruction, not the original text of the command.) pg_get_expr decompiles the internal form of an individual expression, such as the default value for a column. It can be useful when examining the contents of system catalogs. pg_get_viewdef reconstructs the SELECT query that defines a view. Most of these functions come in two variants, one of which can optionally “pretty-print” the result. The pretty-printed format is more readable, but the default format is more likely to be interpreted the same way by future versions of PostgreSQL; avoid using pretty-printed output for dump purposes. Passing false for the pretty-print parameter yields the same result as the variant that does not have the parameter at all.

pg_get_serial_sequence returns the name of the sequence associated with a column, or NULL if no sequence is associated with the column. The first input parameter is a table name with optional schema, and the second parameter is a column name. Because the first parameter is potentially a schema and table, it is not treated as a double-quoted identifier, meaning it is lowercased by default, while the second parameter, being just a column name, is treated as double-quoted and has its case preserved. The function returns a value suitably formatted for passing to the sequence functions (see Section 9.15). This association can be modified or removed with ALTER SEQUENCE OWNED BY. (The function probably should have been called pg_get_owned_sequence; its name reflects the fact that it’s typically used with serial or bigserial columns.)

pg_get_userbyid extracts a role’s name given its OID.

pg_tablespace_databases allows a tablespace to be examined. It returns the set of OIDs of databases that have objects stored in the tablespace. If this function returns any rows, the tablespace is not empty and cannot be dropped. To display the specific objects populating the tablespace, you will need to connect to the databases identified by pg_tablespace_databases and query their pg_class catalogs.

The functions shown in Table 9-48 extract comments previously stored with the COMMENT command. A null value is returned if no comment could be found matching the specified parameters.

### Table 9-48. Comment Information Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>col_description(table_oid, column_number)</td>
<td>text</td>
<td>get comment for a table column</td>
</tr>
<tr>
<td>obj_description(object_oid, catalog_name)</td>
<td>text</td>
<td>get comment for a database object</td>
</tr>
<tr>
<td>obj_description(object_oid)</td>
<td>text</td>
<td>get comment for a database object (deprecated)</td>
</tr>
<tr>
<td>shobj_description(object_oid, catalog_name)</td>
<td>text</td>
<td>get comment for a shared database object</td>
</tr>
</tbody>
</table>

col_description returns the comment for a table column, which is specified by the OID of its table and its column number. obj_description cannot be used for table columns since columns do not have OIDs of their own.

The two-parameter form of obj_description returns the comment for a database object specified by its OID and the name of the containing system catalog. For example, obj_description(123456, ‘pg_class’) would retrieve the comment for a table with OID 123456. The one-parameter form of obj_description requires only the object OID. It is now deprecated since there is no guarantee that OIDs are unique across different system catalogs;
therefore, the wrong comment could be returned.

shobj_description is used just like obj_description only that it is used for retrieving comments on shared objects. Some system catalogs are global to all databases within each cluster and their descriptions are stored globally as well.

The functions shown in Table 9-49 export server internal transaction information to user level. The main use of these functions is to determine which transactions were committed between two snapshots.

### Table 9-49. Transaction IDs and snapshots

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>txid_current()</td>
<td>bigint</td>
<td>get current transaction ID</td>
</tr>
<tr>
<td>txid_current_snapshot()</td>
<td>txid_snapshot</td>
<td>get current snapshot</td>
</tr>
<tr>
<td>txid_snapshot_xmin(txid_snapshot)</td>
<td>bigint</td>
<td>get xmin of snapshot</td>
</tr>
<tr>
<td>txid_snapshot_xmax(txid_snapshot)</td>
<td>bigint</td>
<td>get xmax of snapshot</td>
</tr>
<tr>
<td>txid_snapshot_xip(txid_snapshot)</td>
<td>setof bigint</td>
<td>get in-progress transaction IDs in snapshot</td>
</tr>
<tr>
<td>txid_visible_in_snapshot(txid, txid_snapshot)</td>
<td>boolean</td>
<td>is transaction ID visible in snapshot?</td>
</tr>
</tbody>
</table>

The internal transaction ID type (xid) is 32 bits wide and so it wraps around every 4 billion transactions. However, these functions export a 64-bit format that is extended with an “epoch” counter so that it will not wrap around for the life of an installation. The data type used by these functions, txid_snapshot, stores information about transaction ID visibility at a particular moment in time. Its components are described in Table 9-50.

### Table 9-50. Snapshot components

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xmin</td>
<td>Earliest transaction ID (txid) that is still active. All earlier transactions will either be committed and visible, or rolled back and dead.</td>
</tr>
<tr>
<td>xmax</td>
<td>First as-yet-unassigned txid. All txids later than this one are not yet started as of the time of the snapshot, and thus invisible.</td>
</tr>
<tr>
<td>xip_list</td>
<td>Active txids at the time of the snapshot. All of them are between xmin and xmax. A txid that is xmin &lt;= txid &lt; xmax and not in this list was already completed at the time of the snapshot, and thus either visible or dead according to its commit status.</td>
</tr>
</tbody>
</table>

txid_snapshot’s textual representation is xmin:xmax:xip_list. For example 10:20:10,14,15 means xmin=10, xmax=20, xip_list=10, 14, 15.
9.23. System Administration Functions

Table 9-51 shows the functions available to query and alter run-time configuration parameters.

Table 9-51. Configuration Settings Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>current_setting(setting_name)</td>
<td>text</td>
<td>current value of setting</td>
</tr>
<tr>
<td>set_config(setting_name, new_value, is_local)</td>
<td>text</td>
<td>set parameter and return new value</td>
</tr>
</tbody>
</table>

The function `current_setting` yields the current value of the setting `setting_name`. It corresponds to the SQL command `SHOW`. An example:

SELECT current_setting('datestyle');

```
current_setting
--------------------
ISO, MDY
(1 row)
```

`set_config` sets the parameter `setting_name` to `new_value`. If `is_local` is true, the new value will only apply to the current transaction. If you want the new value to apply for the current session, use `false` instead. The function corresponds to the SQL command `SET`. An example:

SELECT set_config('log_statement_stats', 'off', false);

```
set_config
----------
off
(1 row)
```

The functions shown in Table 9-52 send control signals to other server processes. Use of these functions is restricted to superusers.

Table 9-52. Server Signalling Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_cancel_backend(pid int)</td>
<td>boolean</td>
<td>Cancel a backend’s current query</td>
</tr>
<tr>
<td>pg_reload_conf()</td>
<td>boolean</td>
<td>Cause server processes to reload their configuration files</td>
</tr>
<tr>
<td>pg_rotate_logfile()</td>
<td>boolean</td>
<td>Rotate server’s log file</td>
</tr>
</tbody>
</table>

Each of these functions returns `true` if successful and `false` otherwise.

`pg_cancel_backend` sends a query cancel (SIGINT) signal to a backend process identified by process ID. The process ID of an active backend can be found from the `procpid` column in the `pg_stat_activity` view, or by listing the `postgres` processes on the server with `ps`. 
pg_reload_conf sends a SIGHUP signal to the server, causing the configuration files to be reloaded by all server processes.

pg_rotate_logfile signals the log-file manager to switch to a new output file immediately. This works only when the built-in log collector is running, since otherwise there is no log-file manager subprocess.

The functions shown in Table 9-53 assist in making on-line backups. Use of the first three functions is restricted to superusers.

Table 9-53. Backup Control Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_start_backup(label text)</td>
<td>text</td>
<td>Set up for performing on-line backup</td>
</tr>
<tr>
<td>pg_stop_backup()</td>
<td>text</td>
<td>Finish performing on-line backup</td>
</tr>
<tr>
<td>pg_switch_xlog()</td>
<td>text</td>
<td>Force switch to a new transaction log file</td>
</tr>
<tr>
<td>pg_current_xlog_location()</td>
<td>text</td>
<td>Get current transaction log write location</td>
</tr>
<tr>
<td>pg_current_xlog_insert_location()</td>
<td>text</td>
<td>Get current transaction log insert location</td>
</tr>
<tr>
<td>pg_xlogfile_name_offset(location text)</td>
<td>text, integer</td>
<td>Convert transaction log location string to file name and decimal byte offset within file</td>
</tr>
<tr>
<td>pg_xlogfile_name(location text)</td>
<td>text</td>
<td>Convert transaction log location string to file name</td>
</tr>
</tbody>
</table>

pg_start_backup accepts a single parameter which is an arbitrary user-defined label for the backup. (Typically this would be the name under which the backup dump file will be stored.) The function writes a backup label file into the database cluster’s data directory, and then returns the backup’s starting transaction log location as text. The user need not pay any attention to this result value, but it is provided in case it is of use.

postgres=# select pg_start_backup('label_goes_here');
pg_start_backup
-----------------
0/D4445B8
(1 row)

pg_stop_backup removes the label file created by pg_start_backup, and instead creates a backup history file in the transaction log archive area. The history file includes the label given to pg_start_backup, the starting and ending transaction log locations for the backup, and the starting and ending times of the backup. The return value is the backup’s ending transaction log location (which again might be of little interest). After noting the ending location, the current transaction log insertion point is automatically advanced to the next transaction log file, so that the ending transaction log file can be archived immediately to complete the backup.
pg_switch_xlog moves to the next transaction log file, allowing the current file to be archived (assuming you are using continuous archiving). The result is the ending transaction log location + 1 within the just-completed transaction log file. If there has been no transaction log activity since the last transaction log switch, pg_switch_xlog does nothing and returns the start location of the transaction log file currently in use.

pg_current_xlog_location displays the current transaction log write location in the same format used by the above functions. Similarly, pg_current_xlog_insert_location displays the current transaction log insertion point. The insertion point is the “logical” end of the transaction log at any instant, while the write location is the end of what has actually been written out from the server’s internal buffers. The write location is the end of what can be examined from outside the server, and is usually what you want if you are interested in archiving partially-complete transaction log files. The insertion point is made available primarily for server debugging purposes. These are both read-only operations and do not require superuser permissions.

You can use pg_xlogfile_name_offset to extract the corresponding transaction log file name and byte offset from the results of any of the above functions. For example:

```sql
postgres=# select * from pg_xlogfile_name_offset(pg_stop_backup());

<table>
<thead>
<tr>
<th>file_name</th>
<th>file_offset</th>
</tr>
</thead>
<tbody>
<tr>
<td>00000001000000000000000D</td>
<td>4039624</td>
</tr>
</tbody>
</table>

(1 row)
```

Similarly, pg_xlogfile_name extracts just the transaction log file name. When the given transaction log location is exactly at a transaction log file boundary, both these functions return the name of the preceding transaction log file. This is usually the desired behavior for managing transaction log archiving behavior, since the preceding file is the last one that currently needs to be archived.

For details about proper usage of these functions, see Section 24.3.

The functions shown in Table 9-54 calculate the actual disk space usage of database objects.

### Table 9-54. Database Object Size Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_column_size(any)</td>
<td>int</td>
<td>Number of bytes used to store a particular value (possibly compressed)</td>
</tr>
<tr>
<td>pg_database_size(oid)</td>
<td>bigint</td>
<td>Disk space used by the database with the specified OID</td>
</tr>
<tr>
<td>pg_database_size(name)</td>
<td>bigint</td>
<td>Disk space used by the database with the specified name</td>
</tr>
<tr>
<td>pg_relation_size(oid)</td>
<td>bigint</td>
<td>Disk space used by the table or index with the specified OID</td>
</tr>
<tr>
<td>pg_relation_size(text)</td>
<td>bigint</td>
<td>Disk space used by the table or index with the specified name. The table name can be qualified with a schema name</td>
</tr>
<tr>
<td>pg_size_pretty(bigint)</td>
<td>text</td>
<td>Converts a size in bytes into a human-readable format with size units</td>
</tr>
</tbody>
</table>
Chapter 9. Functions and Operators

### Table 9-55. Generic File Access Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_ls_dir</code> (dirname text)</td>
<td>setof text</td>
<td>List the contents of a directory</td>
</tr>
<tr>
<td><code>pg_read_file</code> (filename text, offset bigint, length bigint)</td>
<td>text</td>
<td>Return the contents of a text file</td>
</tr>
<tr>
<td><code>pg_stat_file</code> (filename text)</td>
<td>record</td>
<td>Return information about a file</td>
</tr>
</tbody>
</table>

**pg_column_size** shows the space used to store any individual data value.

**pg_database_size** and **pg_tablespace_size** accept the OID or name of a database or tablespace, and return the total disk space used therein.

**pg_relation_size** accepts the OID or name of a table, index or toast table, and returns the size in bytes.

**pg_size_pretty** can be used to format the result of one of the other functions in a human-readable way, using kB, MB, GB or TB as appropriate.

**pg_total_relation_size** accepts the OID or name of a table or toast table, and returns the size in bytes of the data and all associated indexes and toast tables.

The functions shown in Table 9-55 provide native file access to files on the machine hosting the server. Only files within the database cluster directory and the `log_directory` can be accessed. Use a relative path for files within the cluster directory, and a path matching the `log_directory` configuration setting for log files. Use of these functions is restricted to superusers.
The functions shown in Table 9-56 manage advisory locks. For details about proper usage of these functions, see Section 13.3.4.

Table 9-56. Advisory Lock Functions

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_advisory_lock(key bigint)</td>
<td>void</td>
<td>Obtain exclusive advisory lock</td>
</tr>
<tr>
<td>pg_advisory_lock(key1 int, key2 int)</td>
<td>void</td>
<td>Obtain exclusive advisory lock</td>
</tr>
<tr>
<td>pg_advisory_lock_shared(key bigint)</td>
<td>void</td>
<td>Obtain shared advisory lock</td>
</tr>
<tr>
<td>pg_advisory_lock_shared(key1 int, key2 int)</td>
<td>void</td>
<td>Obtain shared advisory lock</td>
</tr>
<tr>
<td>pg_try_advisory_lock(key bigint)</td>
<td>boolean</td>
<td>Obtain exclusive advisory lock if available</td>
</tr>
<tr>
<td>pg_try_advisory_lock(key1 int, key2 int)</td>
<td>boolean</td>
<td>Obtain exclusive advisory lock if available</td>
</tr>
<tr>
<td>pg_try_advisory_lock_shared(key bigint)</td>
<td>boolean</td>
<td>Obtain shared advisory lock if available</td>
</tr>
<tr>
<td>pg_try_advisory_lock_shared(key1 int, key2 int)</td>
<td>boolean</td>
<td>Obtain shared advisory lock if available</td>
</tr>
<tr>
<td>pg_advisory_unlock(key bigint)</td>
<td>boolean</td>
<td>Release an exclusive advisory lock</td>
</tr>
<tr>
<td>pg_advisory_unlock(key1 int, key2 int)</td>
<td>boolean</td>
<td>Release an exclusive advisory lock</td>
</tr>
<tr>
<td>pg_advisory_unlock_shared(key bigint)</td>
<td>boolean</td>
<td>Release a shared advisory lock</td>
</tr>
<tr>
<td>pg_advisory_unlock_shared(key1 int, key2 int)</td>
<td>boolean</td>
<td>Release a shared advisory lock</td>
</tr>
<tr>
<td>pg_advisory_unlock_all()</td>
<td>void</td>
<td>Release all advisory locks held by the current session</td>
</tr>
</tbody>
</table>

pg_advisory_lock locks an application-defined resource, which can be identified either by a single 64-bit key value or two 32-bit key values (note that these two key spaces do not overlap). If another session already holds a lock on the same resource, the function will wait until the resource becomes available. The lock is exclusive. Multiple lock requests stack, so that if the same resource is locked three times it must be also unlocked three times to be released for other sessions’ use.

pg_advisory_lock_shared works the same as pg_advisory_lock, except the lock can be
shared with other sessions requesting shared locks. Only would-be exclusive lockers are locked out.

`pg_try_advisory_lock` is similar to `pg_advisory_lock`, except the function will not wait for
the lock to become available. It will either obtain the lock immediately and return `true`, or return `false` if the lock cannot be acquired now.

`pg_try_advisory_lock_shared` works the same as `pg_try_advisory_lock`, except it attempts
to acquire shared rather than exclusive lock.

`pg_advisory_unlock` will release a previously-acquired exclusive advisory lock. It will return `true` if the lock is successfully released. If the lock was in fact not held, it will return `false`, and in addition, an SQL warning will be raised by the server.

`pg_advisory_unlock_shared` works the same as `pg_advisory_unlock`, except to release a
shared advisory lock.

`pg_advisory_unlock_all` will release all advisory locks held by the current session. (This func-
tion is implicitly invoked at session end, even if the client disconnects ungracefully.)
Chapter 10. Type Conversion

SQL statements can, intentionally or not, require mixing of different data types in the same expression. PostgreSQL has extensive facilities for evaluating mixed-type expressions.

In many cases a user will not need to understand the details of the type conversion mechanism. However, the implicit conversions done by PostgreSQL can affect the results of a query. When necessary, these results can be tailored by using explicit type conversion.

This chapter introduces the PostgreSQL type conversion mechanisms and conventions. Refer to the relevant sections in Chapter 8 and Chapter 9 for more information on specific data types and allowed functions and operators.

10.1. Overview

SQL is a strongly typed language. That is, every data item has an associated data type which determines its behavior and allowed usage. PostgreSQL has an extensible type system that is much more general and flexible than other SQL implementations. Hence, most type conversion behavior in PostgreSQL is governed by general rules rather than by ad hoc heuristics. This allows mixed-type expressions to be meaningful even with user-defined types.

The PostgreSQL scanner/parser divides lexical elements into only five fundamental categories: integers, non-integer numbers, strings, identifiers, and key words. Constants of most non-numeric types are first classified as strings. The SQL language definition allows specifying type names with strings, and this mechanism can be used in PostgreSQL to start the parser down the correct path. For example, the query

```
SELECT text 'Origin' AS "label", point '(0,0)' AS "value";
```

<table>
<thead>
<tr>
<th>label</th>
<th>value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Origin</td>
<td>(0,0)</td>
</tr>
</tbody>
</table>
(1 row)

has two literal constants, of type text and point. If a type is not specified for a string literal, then the placeholder type unknown is assigned initially, to be resolved in later stages as described below.

There are four fundamental SQL constructs requiring distinct type conversion rules in the PostgreSQL parser:

Function calls

Much of the PostgreSQL type system is built around a rich set of functions. Functions can have one or more arguments. Since PostgreSQL permits function overloading, the function name alone does not uniquely identify the function to be called; the parser must select the right function based on the data types of the supplied arguments.

Operators

PostgreSQL allows expressions with prefix and postfix unary (one-argument) operators, as well as binary (two-argument) operators. Like functions, operators can be overloaded, and so the same problem of selecting the right operator exists.
Value Storage

SQL INSERT and UPDATE statements place the results of expressions into a table. The expressions in the statement must be matched up with, and perhaps converted to, the types of the target columns.

UNION, CASE, and related constructs

Since all query results from a unionized SELECT statement must appear in a single set of columns, the types of the results of each SELECT clause must be matched up and converted to a uniform set. Similarly, the result expressions of a CASE construct must be converted to a common type so that the CASE expression as a whole has a known output type. The same holds for ARRAY constructs, and for the GREATEST and LEAST functions.

The system catalogs store information about which conversions, called casts, between data types are valid, and how to perform those conversions. Additional casts can be added by the user with the CREATE CAST command. (This is usually done in conjunction with defining new data types. The set of casts between the built-in types has been carefully crafted and is best not altered.)

An additional heuristic is provided in the parser to allow better guesses at proper behavior for SQL standard types. There are several basic type categories defined: boolean, numeric, string, bitstring, datetime, timespan, geometric, network, and user-defined. Each category, with the exception of user-defined, has one or more preferred types which are preferentially selected when there is ambiguity. In the user-defined category, each type is its own preferred type. Ambiguous expressions (those with multiple candidate parsing solutions) can therefore often be resolved when there are multiple possible built-in types, but they will raise an error when there are multiple choices for user-defined types.

All type conversion rules are designed with several principles in mind:

- Implicit conversions should never have surprising or unpredictable outcomes.
- User-defined types, of which the parser has no a priori knowledge, should be “higher” in the type hierarchy. In mixed-type expressions, native types shall always be converted to a user-defined type (of course, only if conversion is necessary).
- User-defined types are not related. Currently, PostgreSQL does not have information available to it on relationships between types, other than hardcoded heuristics for built-in types and implicit relationships based on available functions and casts.
- There should be no extra overhead from the parser or executor if a query does not need implicit type conversion. That is, if a query is well formulated and the types already match up, then the query should proceed without spending extra time in the parser and without introducing unnecessary implicit conversion calls into the query.

Additionally, if a query usually requires an implicit conversion for a function, and if then the user defines a new function with the correct argument types, the parser should use this new function and will no longer do the implicit conversion using the old function.

10.2. Operators

The specific operator to be used in an operator invocation is determined by following the procedure below. Note that this procedure is indirectly affected by the precedence of the involved operators. See
Chapter 10. Type Conversion

Section 4.1.6 for more information.

Operator Type Resolution

1. Select the operators to be considered from the pg_operator system catalog. If an unqualified operator name was used (the usual case), the operators considered are those of the right name and argument count that are visible in the current search path (see Section 5.7.3). If a qualified operator name was given, only operators in the specified schema are considered.

   a. If the search path finds multiple operators of identical argument types, only the one appearing earliest in the path is considered. But operators of different argument types are considered on an equal footing regardless of search path position.

2. Check for an operator accepting exactly the input argument types. If one exists (there can be only one exact match in the set of operators considered), use it.

   a. If one argument of a binary operator invocation is of the unknown type, then assume it is the same type as the other argument for this check. Other cases involving unknown will never find a match at this step.

3. Look for the best match.

   a. Discard candidate operators for which the input types do not match and cannot be converted (using an implicit conversion) to match. unknown literals are assumed to be convertible to anything for this purpose. If only one candidate remains, use it; else continue to the next step.

   b. Run through all candidates and keep those with the most exact matches on input types. (Domains are considered the same as their base type for this purpose.) Keep all candidates if none have any exact matches. If only one candidate remains, use it; else continue to the next step.

   c. Run through all candidates and keep those that accept preferred types (of the input data type’s type category) at the most positions where type conversion will be required. Keep all candidates if none accept preferred types. If only one candidate remains, use it; else continue to the next step.

   d. If any input arguments are unknown, check the type categories accepted at those argument positions by the remaining candidates. At each position, select the string category if any candidate accepts that category. (This bias towards string is appropriate since an unknown-type literal does look like a string.) Otherwise, if all the remaining candidates accept the same type category, select that category; otherwise fail because the correct choice cannot be deduced without more clues. Now discard candidates that do not accept the selected type category. Furthermore, if any candidate accepts a preferred type at a given argument position, discard candidates that accept non-preferred types for that argument.

   e. If only one candidate remains, use it. If no candidate or more than one candidate remains, then fail.

Some examples follow.
Chapter 10. Type Conversion

Example 10-1. Factorial Operator Type Resolution

There is only one factorial operator (postfix !) defined in the standard catalog, and it takes an argument of type bigint. The scanner assigns an initial type of integer to the argument in this query expression:

```
SELECT 40 ! AS "40 factorial";
```

```
40 factorial
------------------
8159152832478977343456112695961158942720000000000
```

So the parser does a type conversion on the operand and the query is equivalent to

```
SELECT CAST(40 AS bigint) ! AS "40 factorial";
```

Example 10-2. String Concatenation Operator Type Resolution

A string-like syntax is used for working with string types as well as for working with complex extension types. Strings with unspecified type are matched with likely operator candidates.

An example with one unspecified argument:

```
SELECT text 'abc' || 'def' AS "text and unknown";
```

```
text and unknown
------------------
abcdef
```

In this case the parser looks to see if there is an operator taking text for both arguments. Since there is, it assumes that the second argument should be interpreted as of type text.

Here is a concatenation on unspecified types:

```
SELECT 'abc' || 'def' AS "unspecified";
```

```
unspecified
----------
abcdef
```

In this case there is no initial hint for which type to use, since no types are specified in the query. So, the parser looks for all candidate operators and finds that there are candidates accepting both string-category and bit-string-category inputs. Since string category is preferred when available, that category is selected, and then the preferred type for strings, text, is used as the specific type to resolve the unknown literals to.

Example 10-3. Absolute-Value and Negation Operator Type Resolution

The PostgreSQL operator catalog has several entries for the prefix operator @, all of which implement absolute-value operations for various numeric data types. One of these entries is for type float8, which is the preferred type in the numeric category. Therefore, PostgreSQL will use that entry when faced with an unknown input:

```
SELECT @ '-4.5' AS "abs";
```
Here the system has implicitly resolved the unknown-type literal as type float8 before applying the chosen operator. We can verify that float8 and not some other type was used:

```
SELECT @ '-4.5e500' AS "abs";
```

ERROR: "-4.5e500" is out of range for type double precision

On the other hand, the prefix operator ~ (bitwise negation) is defined only for integer data types, not for float8. So, if we try a similar case with ~, we get:

```
SELECT ~ '20' AS "negation";
```

ERROR: operator is not unique: ~ "unknown"
HINT: Could not choose a best candidate operator. You might need to add explicit type casts.

This happens because the system cannot decide which of the several possible ~ operators should be preferred. We can help it out with an explicit cast:

```
SELECT ~ CAST('20' AS int8) AS "negation";
```

negation
----------
-21
(1 row)

10.3. Functions

The specific function to be used in a function invocation is determined according to the following steps.

**Function Type Resolution**

1. Select the functions to be considered from the `pg_proc` system catalog. If an unqualified function name was used, the functions considered are those of the right name and argument count that are visible in the current search path (see Section 5.7.3). If a qualified function name was given, only functions in the specified schema are considered.

   a. If the search path finds multiple functions of identical argument types, only the one appearing earliest in the path is considered. But functions of different argument types are considered on an equal footing regardless of search path position.

2. Check for a function accepting exactly the input argument types. If one exists (there can be only one exact match in the set of functions considered), use it. (Cases involving unknown will never find a match at this step.)

3. If no exact match is found, see whether the function call appears to be a special type conversion request. This happens if the function call has just one argument and the function name is the same as the (internal) name of some data type. Furthermore, the function argument must be either an unknown-type literal, or a type that is binary-compatible with the named data type, or a type that could be converted to the named data type by applying that type’s I/O functions (that is, the
conversion is either to or from one of the standard string types). When these conditions are met, the function call is treated as a form of CAST specification.  

4. Look for the best match.

   a. Discard candidate functions for which the input types do not match and cannot be converted (using an implicit conversion) to match. unknown literals are assumed to be convertible to anything for this purpose. If only one candidate remains, use it; else continue to the next step.

   b. Run through all candidates and keep those with the most exact matches on input types. (Domains are considered the same as their base type for this purpose.) Keep all candidates if none have any exact matches. If only one candidate remains, use it; else continue to the next step.

   c. Run through all candidates and keep those that accept preferred types (of the input data type's type category) at the most positions where type conversion will be required. Keep all candidates if none accept preferred types. If only one candidate remains, use it; else continue to the next step.

   d. If any input arguments are unknown, check the type categories accepted at those argument positions by the remaining candidates. At each position, select the string category if any candidate accepts that category. (This bias towards string is appropriate since an unknown-type literal does look like a string.) Otherwise, if all the remaining candidates accept the same type category, select that category; otherwise fail because the correct choice cannot be deduced without more clues. Now discard candidates that do not accept the selected type category. Furthermore, if any candidate accepts a preferred type at a given argument position, discard candidates that accept non-preferred types for that argument.

   e. If only one candidate remains, use it. If no candidate or more than one candidate remains, then fail.

Note that the “best match” rules are identical for operator and function type resolution. Some examples follow.

Example 10-4. Rounding Function Argument Type Resolution

There is only one round function with two arguments. (The first is numeric, the second is integer.) So the following query automatically converts the first argument of type integer to numeric:

```
SELECT round(4, 4);
```

```
round
--------
 4.0000
(1 row)
```

That query is actually transformed by the parser to

```
SELECT round(CAST (4 AS numeric), 4);
```

Since numeric constants with decimal points are initially assigned the type numeric, the following query will require no type conversion and might therefore be slightly more efficient:

```
SELECT round(4.0, 4);
```

---

1. The reason for this step is to support function-style cast specifications in cases where there is not an actual cast function. If there is a cast function, it is conventionally named after its output type, and so there is no need to have a special case. See CREATE CAST for additional commentary.
Example 10-5. Substring Function Type Resolution

There are several `substr` functions, one of which takes types `text` and `integer`. If called with a string constant of unspecified type, the system chooses the candidate function that accepts an argument of the preferred category `string` (namely of type `text`).

```
SELECT substr('1234', 3);
```

```
substr
--------
34
(1 row)
```

If the string is declared to be of type `varchar`, as might be the case if it comes from a table, then the parser will try to convert it to become `text`:

```
SELECT substr(varchar '1234', 3);
```

```
substr
--------
34
(1 row)
```

This is transformed by the parser to effectively become

```
SELECT substr(CAST (varchar '1234' AS text), 3);
```

Note: The parser learns from the `pg_cast` catalog that `text` and `varchar` are binary-compatible, meaning that one can be passed to a function that accepts the other without doing any physical conversion. Therefore, no type conversion call is really inserted in this case.

And, if the function is called with an argument of type `integer`, the parser will try to convert that to `text`:

```
SELECT substr(1234, 3);
```

ERROR: function substr(integer, integer) does not exist
HINT: No function matches the given name and argument types. You might need to add explicit type casts.

This does not work because `integer` does not have an implicit cast to `text`. An explicit cast will work, however:

```
SELECT substr(CAST (1234 AS text), 3);
```

```
substr
--------
34
(1 row)
```
Chapter 10. Type Conversion

10.4. Value Storage

Values to be inserted into a table are converted to the destination column’s data type according to the following steps.

Value Storage Type Conversion

1. Check for an exact match with the target.
2. Otherwise, try to convert the expression to the target type. This will succeed if there is a registered cast between the two types. If the expression is an unknown-type literal, the contents of the literal string will be fed to the input conversion routine for the target type.
3. Check to see if there is a sizing cast for the target type. A sizing cast is a cast from that type to itself. If one is found in the `pg_cast` catalog, apply it to the expression before storing into the destination column. The implementation function for such a cast always takes an extra parameter of type `integer`, which receives the destination column’s `atttypmod` value (typically its declared length, although the interpretation of `atttypmod` varies for different data types), and it may take a third `boolean` parameter that says whether the cast is explicit or implicit. The cast function is responsible for applying any length-dependent semantics such as size checking or truncation.

Example 10-6. character Storage Type Conversion

For a target column declared as `character(20)` the following statement shows that the stored value is sized correctly:

```sql
CREATE TABLE vv (v character(20));
INSERT INTO vv SELECT 'abc' || 'def';
SELECT v, octet_length(v) FROM vv;
```

<table>
<thead>
<tr>
<th>v</th>
<th>octet_length</th>
</tr>
</thead>
<tbody>
<tr>
<td>abcdef</td>
<td>20</td>
</tr>
</tbody>
</table>

What has really happened here is that the two unknown literals are resolved to `text` by default, allowing the `||` operator to be resolved as `text` concatenation. Then the `text` result of the operator is converted to `bpchar` (“blank-padded char”, the internal name of the `character` data type) to match the target column type. (Since the types `text` and `bpchar` are binary-compatible, this conversion does not insert any real function call.) Finally, the sizing function `bpchar(bpchar, integer, boolean)` is found in the system catalog and applied to the operator’s result and the stored column length. This type-specific function performs the required length check and addition of padding spaces.

10.5. UNION, CASE, and Related Constructs

SQL `UNION` constructs must match up possibly dissimilar types to become a single result set. The resolution algorithm is applied separately to each output column of a union query. The `INTERSECT` and `EXCEPT` constructs resolve dissimilar types in the same way as `UNION`. The `CASE`, `ARRAY`, `VALUES`, `GREATEST` and `LEAST` constructs use the identical algorithm to match up their component expressions and select a result data type.
Chapter 10. Type Conversion

Type Resolution for UNION, CASE, and Related Constructs

1. If all inputs are of the same type, and it is not unknown, resolve as that type. Otherwise, replace any domain types in the list with their underlying base types.

2. If all inputs are of type unknown, resolve as type text (the preferred type of the string category). Otherwise, the unknown inputs will be ignored.

3. If the non-unknown inputs are not all of the same type category, fail.

4. Choose the first non-unknown input type which is a preferred type in that category, if there is one.

5. Otherwise, choose the last non-unknown input type that allows all the preceding non-unknown inputs to be implicitly converted to it. (There always is such a type, since at least the first type in the list must satisfy this condition.)

6. Convert all inputs to the selected type. Fail if there is not a conversion from a given input to the selected type.

Some examples follow.

Example 10-7. Type Resolution with Underspecified Types in a Union

```sql
SELECT text 'a' AS "text" UNION SELECT 'b';
```

```
text
------
a
b
```

Here, the unknown-type literal 'b' will be resolved as type text.

Example 10-8. Type Resolution in a Simple Union

```sql
SELECT 1.2 AS "numeric" UNION SELECT 1;
```

```
numeric
--------
1
1.2
```

The literal 1.2 is of type numeric, and the integer value 1 can be cast implicitly to numeric, so that type is used.

Example 10-9. Type Resolution in a Transposed Union

```sql
SELECT 1 AS "real" UNION SELECT CAST('2.2' AS REAL);
```

```
real
-----
1
2.2
```
(2 rows)
Here, since type real cannot be implicitly cast to integer, but integer can be implicitly cast to real, the union result type is resolved as real.
Chapter 11. Indexes

Indexes are a common way to enhance database performance. An index allows the database server to find and retrieve specific rows much faster than it could do without an index. But indexes also add overhead to the database system as a whole, so they should be used sensibly.

11.1. Introduction

Suppose we have a table similar to this:

```sql
CREATE TABLE test1 (
    id integer,
    content varchar
);
```

and the application requires a lot of queries of the form:

```sql
SELECT content FROM test1 WHERE id = constant;
```

With no advance preparation, the system would have to scan the entire `test1` table, row by row, to find all matching entries. If there are a lot of rows in `test1` and only a few rows (perhaps only zero or one) that would be returned by such a query, then this is clearly an inefficient method. But if the system has been instructed to maintain an index on the `id` column, then it can use a more efficient method for locating matching rows. For instance, it might only have to walk a few levels deep into a search tree.

A similar approach is used in most books of non-fiction: terms and concepts that are frequently looked up by readers are collected in an alphabetic index at the end of the book. The interested reader can scan the index relatively quickly and flip to the appropriate page(s), rather than having to read the entire book to find the material of interest. Just as it is the task of the author to anticipate the items that the readers are likely to look up, it is the task of the database programmer to foresee which indexes will be of advantage.

The following command would be used to create the index on the `id` column, as discussed:

```sql
CREATE INDEX test1_id_index ON test1 (id);
```

The name `test1_id_index` can be chosen freely, but you should pick something that enables you to remember later what the index was for.

To remove an index, use the `DROP INDEX` command. Indexes can be added to and removed from tables at any time.

Once an index is created, no further intervention is required: the system will update the index when the table is modified, and it will use the index in queries when it thinks this would be more efficient than a sequential table scan. But you might have to run the `ANALYZE` command regularly to update statistics to allow the query planner to make educated decisions. See Chapter 14 for information about how to find out whether an index is used and when and why the planner might choose not to use an index.

Indexes can also benefit `UPDATE` and `DELETE` commands with search conditions. Indexes can moreover be used in join searches. Thus, an index defined on a column that is part of a join condition can significantly speed up queries with joins.
Creating an index on a large table can take a long time. By default, PostgreSQL allows reads (selects) to occur on the table in parallel with creation of an index, but writes (inserts, updates, deletes) are blocked until the index build is finished. In production environments this is often unacceptable. It is possible to allow writes to occur in parallel with index creation, but there are several caveats to be aware of — for more information see Building Indexes Concurrently.

After an index is created, the system has to keep it synchronized with the table. This adds overhead to data manipulation operations. Therefore indexes that are seldom or never used in queries should be removed.

11.2. Index Types

PostgreSQL provides several index types: B-tree, Hash, GiST and GIN. Each index type uses a different algorithm that is best suited to different types of queries. By default, the `CREATE INDEX` command will create a B-tree index, which fits the most common situations.

B-trees can handle equality and range queries on data that can be sorted into some ordering. In particular, the PostgreSQL query planner will consider using a B-tree index whenever an indexed column is involved in a comparison using one of these operators:

- `<`
- `<=`
- `=`
- `>=`
- `>`

Constructs equivalent to combinations of these operators, such as `BETWEEN` and `IN`, can also be implemented with a B-tree index search. Also, an `IS NULL` condition on an index column can be used with a B-tree index.

The optimizer can also use a B-tree index for queries involving the pattern matching operators `LIKE` and `~` if the pattern is a constant and is anchored to the beginning of the string — for example, `col LIKE 'foo%'` or `col ~ '^foo'`, but not `col LIKE '%bar'`. However, if your server does not use the C locale you will need to create the index with a special operator class to support indexing of pattern-matching queries. See Section 11.9 below. It is also possible to use B-tree indexes for `ILIKE` and `~*`, but only if the pattern starts with non-alphabetic characters, i.e. characters that are not affected by upper/lower case conversion.

Hash indexes can only handle simple equality comparisons. The query planner will consider using a hash index whenever an indexed column is involved in a comparison using the `=` operator. (But hash indexes do not support `IS NULL` searches.) The following command is used to create a hash index:

```
CREATE INDEX name ON table USING hash (column);
```

**Note**: Testing has shown PostgreSQL’s hash indexes to perform no better than B-tree indexes, and the index size and build time for hash indexes is much worse. Furthermore, hash index operations are not presently WAL-logged, so hash indexes might need to be rebuilt with `REINDEX` after a database crash. For these reasons, hash index use is presently discouraged.

GiST indexes are not a single kind of index, but rather an infrastructure within which many different indexing strategies can be implemented. Accordingly, the particular operators with which a GiST
index can be used vary depending on the indexing strategy (the *operator class*). As an example, the standard distribution of PostgreSQL includes GiST operator classes for several two-dimensional geometric data types, which support indexed queries using these operators:

```
<< & << & >> <<| & <<| | & |> | >> 0> <0 ~= &&
```

(See Section 9.11 for the meaning of these operators.) Many other GiST operator classes are available in the `contrib` collection or as separate projects. For more information see Chapter 51.

GIN indexes are inverted indexes which can handle values that contain more than one key, arrays for example. Like GiST, GIN can support many different user-defined indexing strategies and the particular operators with which a GIN index can be used vary depending on the indexing strategy. As an example, the standard distribution of PostgreSQL includes GIN operator classes for one-dimensional arrays, which support indexed queries using these operators:

```
<0 0> = &&
```

(See Section 9.17 for the meaning of these operators.) Many other GIN operator classes are available in the `contrib` collection or as separate projects. For more information see Chapter 52.

### 11.3. Multicolumn Indexes

An index can be defined on more than one column of a table. For example, if you have a table of this form:

```sql
CREATE TABLE test2 (  
    major int,  
    minor int,  
    name varchar
);
```

(say, you keep your `/dev` directory in a database...) and you frequently make queries like:

```
SELECT name FROM test2 WHERE major = constant AND minor = constant;
```

then it might be appropriate to define an index on the columns `major` and `minor` together, e.g.:

```sql
CREATE INDEX test2_mm_idx ON test2 (major, minor);
```
Currently, only the B-tree and GiST index types support multicolumn indexes. Up to 32 columns can be specified. (This limit can be altered when building PostgreSQL; see the file pg_config_manual.h.)

A multicolumn B-tree index can be used with query conditions that involve any subset of the index’s columns, but the index is most efficient when there are constraints on the leading (leftmost) columns. The exact rule is that equality constraints on leading columns, plus any inequality constraints on the first column that does not have an equality constraint, will be used to limit the portion of the index that is scanned. Constraints on columns to the right of these columns are checked in the index, so they save visits to the table proper, but they do not reduce the portion of the index that has to be scanned. For example, given an index on \((a, b, c)\) and a query condition \(\text{WHERE } a = 5 \text{ AND } b >= 42 \text{ AND } c < 77\), the index would have to be scanned from the first entry with \(a = 5\) and \(b = 42\) up through the last entry with \(a = 5\). Index entries with \(c >= 77\) would be skipped, but they’d still have to be scanned through. This index could in principle be used for queries that have constraints on \(b\) and/or \(c\) with no constraint on \(a\) — but the entire index would have to be scanned, so in most cases the planner would prefer a sequential table scan over using the index.

A multicolumn GiST index can be used with query conditions that involve any subset of the index’s columns. Conditions on additional columns restrict the entries returned by the index, but the condition on the first column is the most important one for determining how much of the index needs to be scanned. A GiST index will be relatively ineffective if its first column has only a few distinct values, even if there are many distinct values in additional columns.

Of course, each column must be used with operators appropriate to the index type; clauses that involve other operators will not be considered.

Multicolumn indexes should be used sparingly. In most situations, an index on a single column is sufficient and saves space and time. Indexes with more than three columns are unlikely to be helpful unless the usage of the table is extremely stylized. See also Section 11.5 for some discussion of the merits of different index setups.

11.4. Indexes and ORDER BY

In addition to simply finding the rows to be returned by a query, an index may be able to deliver them in a specific sorted order. This allows a query’s ORDER BY specification to be met without a separate sorting step. Of the index types currently supported by PostgreSQL, only B-tree can produce sorted output — the other index types return matching rows in an unspecified, implementation-dependent order.

The planner will consider satisfying an ORDER BY specification either by scanning any available index that matches the specification, or by scanning the table in physical order and doing an explicit sort. For a query that requires scanning a large fraction of the table, the explicit sort is likely to be faster because it requires less disk I/O due to a better-ordered access pattern. Indexes are more useful when only a few rows need be fetched. An important special case is ORDER BY in combination with LIMIT \(n\): an explicit sort will have to process all the data to identify the first \(n\) rows, but if there is an index matching the ORDER BY then the first \(n\) rows can be retrieved directly, without scanning the remainder at all.

By default, B-tree indexes store their entries in ascending order with nulls last. This means that a forward scan of an index on a column \(x\) produces output satisfying ORDER BY \(x\) (or more verbosely, ORDER BY \(x\) ASC NULLS LAST). The index can also be scanned backward, producing output satisfying ORDER BY \(x\) DESC (or more verbosely, ORDER BY \(x\) DESC NULLS FIRST, since NULLS FIRST is the default for ORDER BY DESC).
You can adjust the ordering of a B-tree index by including the options `ASC`, `DESC`, `NULLS FIRST`, and/or `NULLS LAST` when creating the index; for example:

```sql
CREATE INDEX test2_info_nulls_low ON test2 (info NULLS FIRST);
CREATE INDEX test3_desc_index ON test3 (id DESC NULLS LAST);
```

An index stored in ascending order with nulls first can satisfy either `ORDER BY x ASC NULLS FIRST` or `ORDER BY x DESC NULLS LAST` depending on which direction it is scanned in.

You might wonder why bother providing all four options, when two options together with the possibility of backward scan would cover all the variants of `ORDER BY`. In single-column indexes the options are indeed redundant, but in multicolumn indexes they can be useful. Consider a two-column index on `(x, y)`: this can satisfy `ORDER BY x, y` if we scan forward, or `ORDER BY x DESC, y DESC` if we scan backward. But it might be that the application frequently needs to use `ORDER BY x ASC, y DESC`. There is no way to get that ordering from a regular index, but it is possible if the index is defined as `(x ASC, y DESC)` or `(x DESC, y ASC).

Obviously, indexes with non-default sort orderings are a fairly specialized feature, but sometimes they can produce tremendous speedups for certain queries. Whether it’s worth keeping such an index depends on how often you use queries that require a special sort ordering.

### 11.5. Combining Multiple Indexes

A single index scan can only use query clauses that use the index’s columns with operators of its operator class and are joined with `AND`. For example, given an index on `(a, b)` a query condition like `WHERE a = 5 AND b = 6` could use the index, but a query like `WHERE a = 5 OR b = 6` could not directly use the index.

Beginning in release 8.1, PostgreSQL has the ability to combine multiple indexes (including multiple uses of the same index) to handle cases that cannot be implemented by single index scans. The system can form `AND` and `OR` conditions across several index scans. For example, a query like `WHERE x = 42 OR x = 47 OR x = 53 OR x = 99` could be broken down into four separate scans of an index on `x`, each scan using one of the query clauses. The results of these scans are then ORed together to produce the result. Another example is that if we have separate indexes on `x` and `y`, one possible implementation of a query like `WHERE x = 5 AND y = 6` is to use each index with the appropriate query clause and then `AND` together the index results to identify the result rows.

To combine multiple indexes, the system scans each needed index and prepares a `bitmap` in memory giving the locations of table rows that are reported as matching that index’s conditions. The bitmaps are then `AND`ed and `OR`ed together as needed by the query. Finally, the actual table rows are visited and returned. The table rows are visited in physical order, because that is how the bitmap is laid out; this means that any ordering of the original indexes is lost, and so a separate sort step will be needed if the query has an `ORDER BY` clause. For this reason, and because each additional index scan adds extra time, the planner will sometimes choose to use a simple index scan even though additional indexes are available that could have been used as well.

In all but the simplest applications, there are various combinations of indexes that might be useful, and the database developer must make trade-offs to decide which indexes to provide. Sometimes multicolumn indexes are best, but sometimes it’s better to create separate indexes and rely on the index-combination feature. For example, if your workload includes a mix of queries that sometimes involve only column `x`, sometimes only column `y`, and sometimes both columns, you might choose to create two separate indexes on `x` and `y`, relying on index combination to process the queries that use both columns. You could also create a multicolumn index on `(x, y)`. This index would typically be more efficient than index combination for queries involving both columns, but as discussed in Section...
11.3. it would be almost useless for queries involving only y, so it could not be the only index. A combination of the multicolumn index and a separate index on y would serve reasonably well. For queries involving only x, the multicolumn index could be used, though it would be larger and hence slower than an index on x alone. The last alternative is to create all three indexes, but this is probably only reasonable if the table is searched much more often than it is updated and all three types of query are common. If one of the types of query is much less common than the others, you’d probably settle for creating just the two indexes that best match the common types.

11.6. Unique Indexes

Indexes can also be used to enforce uniqueness of a column’s value, or the uniqueness of the combined values of more than one column.

```sql
CREATE UNIQUE INDEX name ON table (column [, ...]);
```

Currently, only B-tree indexes can be declared unique.

When an index is declared unique, multiple table rows with equal indexed values will not be allowed. Null values are not considered equal. A multicolumn unique index will only reject cases where all of the indexed columns are equal in two rows.

PostgreSQL automatically creates a unique index when a unique constraint or a primary key is defined for a table. The index covers the columns that make up the primary key or unique columns (a multicolumn index, if appropriate), and is the mechanism that enforces the constraint.

**Note:** The preferred way to add a unique constraint to a table is `ALTER TABLE ... ADD CONSTRAINT`. The use of indexes to enforce unique constraints could be considered an implementation detail that should not be accessed directly. One should, however, be aware that there's no need to manually create indexes on unique columns; doing so would just duplicate the automatically-created index.

11.7. Indexes on Expressions

An index column need not be just a column of the underlying table, but can be a function or scalar expression computed from one or more columns of the table. This feature is useful to obtain fast access to tables based on the results of computations.

For example, a common way to do case-insensitive comparisons is to use the `lower` function:

```sql
SELECT * FROM test1 WHERE lower(col1) = 'value';
```

This query can use an index, if one has been defined on the result of the `lower(col1)` operation:

```sql
CREATE INDEX test1_lower_col1_idx ON test1 (lower(col1));
```

If we were to declare this index `UNIQUE`, it would prevent creation of rows whose `col1` values differ only in case, as well as rows whose `col1` values are actually identical. Thus, indexes on expressions can be used to enforce constraints that are not definable as simple unique constraints.

As another example, if one often does queries like this:
Chapter 11. Indexes

SELECT * FROM people WHERE (first_name || ' ' || last_name) = 'John Smith';
then it might be worth creating an index like this:

CREATE INDEX people_names ON people ((first_name || ' ' || last_name));

The syntax of the CREATE INDEX command normally requires writing parentheses around index expressions, as shown in the second example. The parentheses can be omitted when the expression is just a function call, as in the first example.

Index expressions are relatively expensive to maintain, because the derived expression(s) must be computed for each row upon insertion and whenever it is updated. However, the index expressions are not recomputed during an indexed search, since they are already stored in the index. In both examples above, the system sees the query as just WHERE indexedcolumn = 'constant’ and so the speed of the search is equivalent to any other simple index query. Thus, indexes on expressions are useful when retrieval speed is more important than insertion and update speed.

11.8. Partial Indexes

A partial index is an index built over a subset of a table; the subset is defined by a conditional expression (called the predicate of the partial index). The index contains entries for only those table rows that satisfy the predicate. Partial indexes are a specialized feature, but there are several situations in which they are useful.

One major reason for using a partial index is to avoid indexing common values. Since a query searching for a common value (one that accounts for more than a few percent of all the table rows) will not use the index anyway, there is no point in keeping those rows in the index at all. This reduces the size of the index, which will speed up queries that do use the index. It will also speed up many table update operations because the index does not need to be updated in all cases. Example 11-1 shows a possible application of this idea.

Example 11-1. Setting up a Partial Index to Exclude Common Values

Suppose you are storing web server access logs in a database. Most accesses originate from the IP address range of your organization but some are from elsewhere (say, employees on dial-up connections). If your searches by IP are primarily for outside accesses, you probably do not need to index the IP range that corresponds to your organization’s subnet.

Assume a table like this:

```sql
CREATE TABLE access_log {
    url varchar,
    client_ip inet,
    ...
};
```

To create a partial index that suits our example, use a command such as this:

```sql
CREATE INDEX access_log_client_ip_ix ON access_log (client_ip)
    WHERE NOT (client_ip > inet '192.168.100.0' AND client_ip < inet '192.168.100.255');
```

A typical query that can use this index would be:

```sql
SELECT * FROM access_log WHERE url = '/index.html' AND client_ip = inet '212.78.10.32';
```

A query that cannot use this index is:
Chapter 11. Indexes

SELECT * FROM access_log WHERE client_ip = inet '192.168.100.23';

Observe that this kind of partial index requires that the common values be predetermined. If the distribution of values is inherent (due to the nature of the application) and static (not changing over time), this is not difficult, but if the common values are merely due to the coincidental data load this can require a lot of maintenance work to change the index definition from time to time.

Another possible use for a partial index is to exclude values from the index that the typical query workload is not interested in; this is shown in Example 11-2. This results in the same advantages as listed above, but it prevents the “uninteresting” values from being accessed via that index at all, even if an index scan might be profitable in that case. Obviously, setting up partial indexes for this kind of scenario will require a lot of care and experimentation.

Example 11-2. Setting up a Partial Index to Exclude Uninteresting Values

If you have a table that contains both billed and unbilled orders, where the unbilled orders take up a small fraction of the total table and yet those are the most-accessed rows, you can improve performance by creating an index on just the unbilled rows. The command to create the index would look like this:

CREATE INDEX orders_unbilled_index ON orders (order_nr)
WHERE billed is not true;

A possible query to use this index would be:

SELECT * FROM orders WHERE billed is not true AND order_nr < 10000;

However, the index can also be used in queries that do not involve order_nr at all, e.g.:

SELECT * FROM orders WHERE billed is not true AND amount > 5000.00;

This is not as efficient as a partial index on the amount column would be, since the system has to scan the entire index. Yet, if there are relatively few unbilled orders, using this partial index just to find the unbilled orders could be a win.

Note that this query cannot use this index:

SELECT * FROM orders WHERE order_nr = 3501;

The order 3501 might be among the billed or among the unbilled orders.

Example 11-2 also illustrates that the indexed column and the column used in the predicate do not need to match. PostgreSQL supports partial indexes with arbitrary predicates, so long as only columns of the table being indexed are involved. However, keep in mind that the predicate must match the conditions used in the queries that are supposed to benefit from the index. To be precise, a partial index can be used in a query only if the system can recognize that the WHERE condition of the query mathematically implies the predicate of the index. PostgreSQL does not have a sophisticated theorem prover that can recognize mathematically equivalent expressions that are written in different forms. (Not only is such a general theorem prover extremely difficult to create, it would probably be too slow to be of any real use.) The system can recognize simple inequality implications, for example “x < 1” implies “x < 2”; otherwise the predicate condition must exactly match part of the query’s WHERE condition or the index will not be recognized to be usable. Matching takes place at query planning time, not at run time. As a result, parameterized query clauses will not work with a partial index. For example a prepared query with a parameter might specify “x < ?” which will never imply “x < 2” for all possible values of the parameter.
Chapter 11. Indexes

A third possible use for partial indexes does not require the index to be used in queries at all. The idea here is to create a unique index over a subset of a table, as in Example 11-3. This enforces uniqueness among the rows that satisfy the index predicate, without constraining those that do not.

Example 11-3. Setting up a Partial Unique Index

Suppose that we have a table describing test outcomes. We wish to ensure that there is only one “successful” entry for a given subject and target combination, but there might be any number of “unsuccessful” entries. Here is one way to do it:

```sql
CREATE TABLE tests (
    subject text,
    target text,
    success boolean,
    ...
);

CREATE UNIQUE INDEX tests_success_constraint ON tests (subject, target) WHERE success;
```

This is a particularly efficient way of doing it when there are few successful tests and many unsuccessful ones.

Finally, a partial index can also be used to override the system’s query plan choices. Also, data sets with peculiar distributions might cause the system to use an index when it really should not. In that case the index can be set up so that it is not available for the offending query. Normally, PostgreSQL makes reasonable choices about index usage (e.g., it avoids them when retrieving common values, so the earlier example really only saves index size, it is not required to avoid index usage), and grossly incorrect plan choices are cause for a bug report.

Keep in mind that setting up a partial index indicates that you know at least as much as the query planner knows, in particular you know when an index might be profitable. Forming this knowledge requires experience and understanding of how indexes in PostgreSQL work. In most cases, the advantage of a partial index over a regular index will not be much.

More information about partial indexes can be found in The case for partial indexes, Partial indexing in POSTGRES: research project, and Generalized Partial Indexes (cached version).

11.9. Operator Classes and Operator Families

An index definition can specify an operator class for each column of an index.

```
CREATE INDEX name ON table (column opclass [sort options] [, ...]);
```

The operator class identifies the operators to be used by the index for that column. For example, a B-tree index on the type int4 would use the int4_ops class; this operator class includes comparison functions for values of type int4. In practice the default operator class for the column’s data type is usually sufficient. The main point of having operator classes is that for some data types, there could be more than one meaningful index behavior. For example, we might want to sort a complex-number data type either by absolute value or by real part. We could do this by defining two operator classes for the data type and then selecting the proper class when making an index. The operator class determines the basic sort ordering (which can then be modified by adding sort options ASC/DESC and/or NULLS FIRST/NULLS LAST).
There are also some built-in operator classes besides the default ones:

- The operator classes `text_pattern_ops`, `varchar_pattern_ops`, `bpchar_pattern_ops`, and `name_pattern_ops` support B-tree indexes on the types `text`, `varchar`, `char`, and `name`, respectively. The difference from the default operator classes is that the values are compared strictly character by character rather than according to the locale-specific collation rules. This makes these operator classes suitable for use by queries involving pattern matching expressions (LIKE or POSIX regular expressions) when the server does not use the standard “C” locale. As an example, you might index a `varchar` column like this:

  ```sql
  CREATE INDEX test_index ON test_table (col varchar_pattern_ops);
  ```

  Note that you should also create an index with the default operator class if you want queries involving ordinary comparisons to use an index. Such queries cannot use the `xxx_pattern_ops` operator classes. It is allowed to create multiple indexes on the same column with different operator classes. If you do use the C locale, you do not need the `xxx_pattern_ops` operator classes, because an index with the default operator class is usable for pattern-matching queries in the C locale.

The following query shows all defined operator classes:

```sql
SELECT am.amname AS index_method,
       opc.opcname AS opclass_name
FROM pg_am am, pg_opclass opc
WHERE opc.opcmethod = am.oid
ORDER BY index_method, opclass_name;
```

An operator class is actually just a subset of a larger structure called an operator family. In cases where several data types have similar behaviors, it is frequently useful to define cross-data-type operators and allow these to work with indexes. To do this, the operator classes for each of the types must be grouped into the same operator family. The cross-type operators are members of the family, but are not associated with any single class within the family.

This query shows all defined operator families and all the operators included in each family:

```sql
SELECT am.amname AS index_method,
       opf.opfname AS opfamily_name,
       amop.amopopr::regoperator AS opfamily_operator
FROM pg_am am, pg_opfamily opf, pg_amop amop
WHERE opf.opfmethod = am.oid AND
      amop.amopfamily = opf.oid
ORDER BY index_method, opfamily_name, opfamily_operator;
```

### 11.10. Examining Index Usage

Although indexes in PostgreSQL do not need maintenance and tuning, it is still important to check which indexes are actually used by the real-life query workload. Examining index usage for an individual query is done with the `EXPLAIN` command; its application for this purpose is illustrated in Section 14.1. It is also possible to gather overall statistics about index usage in a running server, as described in Section 26.2.
Chapter 11. Indexes

It is difficult to formulate a general procedure for determining which indexes to set up. There are a number of typical cases that have been shown in the examples throughout the previous sections. A good deal of experimentation will be necessary in most cases. The rest of this section gives some tips for that.

- Always run `ANALYZE` first. This command collects statistics about the distribution of the values in the table. This information is required to guess the number of rows returned by a query, which is needed by the planner to assign realistic costs to each possible query plan. In absence of any real statistics, some default values are assumed, which are almost certain to be inaccurate. Examining an application’s index usage without having run `ANALYZE` is therefore a lost cause.

- Use real data for experimentation. Using test data for setting up indexes will tell you what indexes you need for the test data, but that is all.

  It is especially fatal to use very small test data sets. While selecting 1000 out of 100000 rows could be a candidate for an index, selecting 1 out of 100 rows will hardly be, because the 100 rows will probably fit within a single disk page, and there is no plan that can beat sequentially fetching 1 disk page.

  Also be careful when making up test data, which is often unavoidable when the application is not in production use yet. Values that are very similar, completely random, or inserted in sorted order will skew the statistics away from the distribution that real data would have.

- When indexes are not used, it can be useful for testing to force their use. There are run-time parameters that can turn off various plan types (see Section 18.6.1). For instance, turning off sequential scans (`enable_seqscan`) and nested-loop joins (`enable_nestloop`), which are the most basic plans, will force the system to use a different plan. If the system still chooses a sequential scan or nested-loop join then there is probably a more fundamental reason why the index is not used; for example, the query condition does not match the index. (What kind of query can use what kind of index is explained in the previous sections.)

- If forcing index usage does use the index, then there are two possibilities: Either the system is right and using the index is indeed not appropriate, or the cost estimates of the query plans are not reflecting reality. So you should time your query with and without indexes. The `EXPLAIN ANALYZE` command can be useful here.

- If it turns out that the cost estimates are wrong, there are, again, two possibilities. The total cost is computed from the per-row costs of each plan node times the selectivity estimate of the plan node. The costs estimated for the plan nodes can be adjusted via run-time parameters (described in Section 18.6.2). An inaccurate selectivity estimate is due to insufficient statistics. It might be possible to improve this by tuning the statistics-gathering parameters (see `ALTER TABLE`).

  If you do not succeed in adjusting the costs to be more appropriate, then you might have to resort to forcing index usage explicitly. You might also want to contact the PostgreSQL developers to examine the issue.
Chapter 12. Full Text Search

12.1. Introduction

Full Text Searching (or just text search) provides the capability to identify natural-language documents that satisfy a query, and optionally to sort them by relevance to the query. The most common type of search is to find all documents containing given query terms and return them in order of their similarity to the query. Notions of query and similarity are very flexible and depend on the specific application. The simplest search considers query as a set of words and similarity as the frequency of query words in the document.

Textual search operators have existed in databases for years. PostgreSQL has ~, ~*, LIKE, and ILIKE operators for textual data types, but they lack many essential properties required by modern information systems:

• There is no linguistic support, even for English. Regular expressions are not sufficient because they cannot easily handle derived words, e.g., satisfies and satisfy. You might miss documents that contain satisfies, although you probably would like to find them when searching for satisfy. It is possible to use OR to search for multiple derived forms, but this is tedious and error-prone (some words can have several thousand derivatives).
• They provide no ordering (ranking) of search results, which makes them ineffective when thousands of matching documents are found.
• They tend to be slow because there is no index support, so they must process all documents for every search.

Full text indexing allows documents to be preprocessed and an index saved for later rapid searching. Preprocessing includes:

 Parsing documents into tokens. It is useful to identify various classes of tokens, e.g. numbers, words, complex words, email addresses, so that they can be processed differently. In principle token classes depend on the specific application, but for most purposes it is adequate to use a predefined set of classes. PostgreSQL uses a parser to perform this step. A standard parser is provided, and custom parsers can be created for specific needs.

 Converting tokens into lexemes. A lexeme is a string, just like a token, but it has been normalized so that different forms of the same word are made alike. For example, normalization almost always includes folding upper-case letters to lower-case, and often involves removal of suffixes (such as s or es in English). This allows searches to find variant forms of the same word, without tediously entering all the possible variants. Also, this step typically eliminates stop words, which are words that are so common that they are useless for searching. (In short, then, tokens are raw fragments of the document text, while lexemes are words that are believed useful for indexing and searching.) PostgreSQL uses dictionaries to perform this step. Various standard dictionaries are provided, and custom ones can be created for specific needs.

 Storing preprocessed documents optimized for searching. For example, each document can be represented as a sorted array of normalized lexemes. Along with the lexemes it is often desirable to store positional information to use for proximity ranking, so that a document that contains a more “dense” region of query words is assigned a higher rank than one with scattered query words.

Dictionaries allow fine-grained control over how tokens are normalized. With appropriate dictionaries, you can:
- Define stop words that should not be indexed.
- Map synonyms to a single word using Ispell.
- Map phrases to a single word using a thesaurus.
- Map different variations of a word to a canonical form using an Ispell dictionary.
- Map different variations of a word to a canonical form using Snowball stemmer rules.

A data type `tsvector` is provided for storing preprocessed documents, along with a type `tsquery` for representing processed queries (Section 8.11). There are many functions and operators available for these data types (Section 9.13), the most important of which is the match operator `@@`, which we introduce in Section 12.1.2. Full text searches can be accelerated using indexes (Section 12.9).

### 12.1.1. What Is a Document?

A *document* is the unit of searching in a full text search system; for example, a magazine article or email message. The text search engine must be able to parse documents and store associations of lexemes (key words) with their parent document. Later, these associations are used to search for documents that contain query words.

For searches within PostgreSQL, a document is normally a textual field within a row of a database table, or possibly a combination (concatenation) of such fields, perhaps stored in several tables or obtained dynamically. In other words, a document can be constructed from different parts for indexing and it might not be stored anywhere as a whole. For example:

```sql
SELECT title || ' ' || author || ' ' || abstract || ' ' || body AS document
FROM messages
WHERE mid = 12;

SELECT m.title || ' ' || m.author || ' ' || m.abstract || ' ' || d.body AS document
FROM messages m, docs d
WHERE mid = did AND mid = 12;
```

**Note:** Actually, in these example queries, `coalesce` should be used to prevent a single `NULL` attribute from causing a `NULL` result for the whole document.

Another possibility is to store the documents as simple text files in the file system. In this case, the database can be used to store the full text index and to execute searches, and some unique identifier can be used to retrieve the document from the file system. However, retrieving files from outside the database requires superuser permissions or special function support, so this is usually less convenient than keeping all the data inside PostgreSQL. Also, keeping everything inside the database allows easy access to document metadata to assist in indexing and display.

For text search purposes, each document must be reduced to the preprocessed `tsvector` format. Searching and ranking are performed entirely on the `tsvector` representation of a document — the original text need only be retrieved when the document has been selected for display to a user. We therefore often speak of the `tsvector` as being the document, but of course it is only a compact representation of the full document.
12.1.2. Basic Text Matching

Full text searching in PostgreSQL is based on the match operator @@, which returns true if a \texttt{tsvector} (document) matches a \texttt{tsquery} (query). It doesn’t matter which data type is written first:

```
SELECT 'a fat cat sat on a mat and ate a fat rat':tsvector @@ 'cat & rat':tsquery;
```

```
?column?
----------
t
```

```
SELECT 'fat & cow':tsquery @@ 'a fat cat sat on a mat and ate a fat rat':tsvector;
```

```
?column?
----------
f
```

As the above example suggests, a \texttt{tsquery} is not just raw text, any more than a \texttt{tsvector} is. A \texttt{tsquery} contains search terms, which must be already-normalized lexemes, and may combine multiple terms using AND, OR, and NOT operators. (For details see Section 8.11.) There are functions \texttt{to\_tsquery} and \texttt{plainto\_tsquery} that are helpful in converting user-written text into a proper \texttt{tsquery}, for example by normalizing words appearing in the text. Similarly, \texttt{to\_tsvector} is used to parse and normalize a document string. So in practice a text search match would look more like this:

```
SELECT to\_tsvector('fat cats ate fat rats') @@ to\_tsquery('fat & rat');
```

```
?column?
----------
t
```

Observe that this match would not succeed if written as

```
SELECT 'fat cats ate fat rats':tsvector @@ to\_tsquery('fat & rat');
```

```
?column?
----------
f
```

since here no normalization of the word \texttt{rats} will occur. The elements of a \texttt{tsvector} are lexemes, which are assumed already normalized, so \texttt{rats} does not match \texttt{rat}.

The @@ operator also supports \texttt{text} input, allowing explicit conversion of a text string to \texttt{tsvector} or \texttt{tsquery} to be skipped in simple cases. The variants available are:

\texttt{tsvector @@ tsquery}
\texttt{tsquery @@ tsvector}
\texttt{text @@ tsquery}
\texttt{text @@ text}

The first two of these we saw already. The form \texttt{text @@ tsquery} is equivalent to \texttt{to\_tsvector(x) @@ y}. The form \texttt{text @@ text} is equivalent to \texttt{to\_tsvector(x) @@ plainto\_tsquery(y)}.
Chapter 12. Full Text Search

12.1.3. Configurations

The above are all simple text search examples. As mentioned before, full text search functionality includes the ability to do many more things: skip indexing certain words (stop words), process synonyms, and use sophisticated parsing, e.g. parse based on more than just white space. This functionality is controlled by text search configurations. PostgreSQL comes with predefined configurations for many languages, and you can easily create your own configurations. (psql’s \dF command shows all available configurations.)

During installation an appropriate configuration is selected and default_text_search_config is set accordingly in postgresql.conf. If you are using the same text search configuration for the entire cluster you can use the value in postgresql.conf. To use different configurations throughout the cluster but the same configuration within any one database, use ALTER DATABASE ... SET. Otherwise, you can set default_text_search_config in each session.

Each text search function that depends on a configuration has an optional regconfig argument, so that the configuration to use can be specified explicitly. default_text_search_config is used only when this argument is omitted.

To make it easier to build custom text search configurations, a configuration is built up from simpler database objects. PostgreSQL’s text search facility provides four types of configuration-related database objects:

- **Text search parsers** break documents into tokens and classify each token (for example, as words or numbers).
- **Text search dictionaries** convert tokens to normalized form and reject stop words.
- **Text search templates** provide the functions underlying dictionaries. (A dictionary simply specifies a template and a set of parameters for the template.)
- **Text search configurations** select a parser and a set of dictionaries to use to normalize the tokens produced by the parser.

Text search parsers and templates are built from low-level C functions; therefore it requires C programming ability to develop new ones, and superuser privileges to install one into a database. (There are examples of add-on parsers and templates in the contrib/ area of the PostgreSQL distribution.) Since dictionaries and configurations just parameterize and connect together some underlying parsers and templates, no special privilege is needed to create a new dictionary or configuration. Examples of creating custom dictionaries and configurations appear later in this chapter.

12.2. Tables and Indexes

The examples in the previous section illustrated full text matching using simple constant strings. This section shows how to search table data, optionally using indexes.

12.2.1. Searching a Table

It is possible to do full text search with no index. A simple query to print the title of each row that contains the word friend in its body field is:

```
SELECT title
FROM pgweb
WHERE to_tsvector('english', body) @@ to_tsquery('english', 'friend');
```
This will also find related words such as friends and friendly, since all these are reduced to the same normalized lexeme.

The query above specifies that the english configuration is to be used to parse and normalize the strings. Alternatively we could omit the configuration parameters:

```sql
SELECT title
FROM pgweb
WHERE to_tsvector(body) @@ to_tsquery('friend');
```

This query will use the configuration set by default_text_search_config.

A more complex example is to select the ten most recent documents that contain create and table in the title or body:

```sql
SELECT title
FROM pgweb
WHERE to_tsvector(title || ' ' || body) @@ to_tsquery('create & table')
ORDER BY last_mod_date DESC LIMIT 10;
```

For clarity we omitted the coalesce function calls which would be needed to find rows that contain NULL in one of the two fields.

Although these queries will work without an index, most applications will find this approach too slow, except perhaps for occasional ad-hoc searches. Practical use of text searching usually requires creating an index.

### 12.2.2. Creating Indexes

We can create a GIN index (Section 12.9) to speed up text searches:

```sql
CREATE INDEX pgweb_idx ON pgweb USING gin(to_tsvector('english', body));
```

Notice that the 2-argument version of `to_tsvector` is used. Only text search functions that specify a configuration name can be used in expression indexes (Section 11.7). This is because the index contents must be unaffected by default_text_search_config. If they were affected, the index contents might be inconsistent because different entries could contain tsvector that were created with different text search configurations, and there would be no way to guess which was which. It would be impossible to dump and restore such an index correctly.

Because the two-argument version of `to_tsvector` was used in the index above, only a query reference that uses the 2-argument version of `to_tsvector` with the same configuration name will use that index. That is, WHERE `to_tsvector('english', body) @@ 'a & b'` can use the index, but WHERE `to_tsvector(body) @@ 'a & b'` cannot. This ensures that an index will be used only with the same configuration used to create the index entries.

It is possible to set up more complex expression indexes wherein the configuration name is specified by another column, e.g.:

```sql
CREATE INDEX pgweb_idx ON pgweb USING gin(to_tsvector(config_name, body));
```

where `config_name` is a column in the `pgweb` table. This allows mixed configurations in the same index while recording which configuration was used for each index entry. This would be useful, for example, if the document collection contained documents in different languages. Again, queries that are to use the index must be phrased to match, e.g. WHERE `to_tsvector(config_name, body) @@ 'a & b'`. 
Indexes can even concatenate columns:

```sql
CREATE INDEX pgweb_idx ON pgweb USING gin(to_tsvector('english', title || ' ' || body));
```

Another approach is to create a separate `tsvector` column to hold the output of `to_tsvector`. This example is a concatenation of `title` and `body`, using `coalesce` to ensure that one field will still be indexed when the other is `NULL`:

```sql
ALTER TABLE pgweb ADD COLUMN textsearchable_index_col tsvector;
UPDATE pgweb SET textsearchable_index_col =
    to_tsvector('english', coalesce(title,"") || ' ' || coalesce(body,""));
```

Then we create a GIN index to speed up the search:

```sql
CREATE INDEX textsearch_idx ON pgweb USING gin(textsearchable_index_col);
```

Now we are ready to perform a fast full text search:

```sql
SELECT title
FROM pgweb
WHERE textsearchable_index_col @@ to_tsquery('create & table')
ORDER BY last_mod_date DESC LIMIT 10;
```

When using a separate column to store the `tsvector` representation, it is necessary to create a trigger to keep the `tsvector` column current anytime `title` or `body` changes. Section 12.4.3 explains how to do that.

One advantage of the separate-column approach over an expression index is that it is not necessary to explicitly specify the text search configuration in queries in order to make use of the index. As shown in the example above, the query can depend on `default_text_search_config`. Another advantage is that searches will be faster, since it will not be necessary to redo the `to_tsvector` calls to verify index matches. (This is more important when using a GiST index than a GIN index; see Section 12.9.) The expression-index approach is simpler to set up, however, and it requires less disk space since the `tsvector` representation is not stored explicitly.

### 12.3. Controlling Text Search

To implement full text searching there must be a function to create a `tsvector` from a document and a `tsquery` from a user query. Also, we need to return results in a useful order, so we need a function that compares documents with respect to their relevance to the query. It’s also important to be able to display the results nicely. PostgreSQL provides support for all of these functions.

#### 12.3.1. Parsing Documents

PostgreSQL provides the function `to_tsvector` for converting a document to the `tsvector` data type.

```
to_tsvector([ config regconfig, ] document text) returns tsvector
```
Chapter 12. Full Text Search

to_tsvector parses a textual document into tokens, reduces the tokens to lexemes, and returns a tsvector which lists the lexemes together with their positions in the document. The document is processed according to the specified or default text search configuration. Here is a simple example:

```sql
SELECT to_tsvector('english', 'a fat cat sat on a mat - it ate a fat rats');
```

```plaintext
to_tsvector
-----------------------------------------------------
'ate':9 'cat':3 'fat':2,11 'mat':7 'rat':12 'sat':4
```

In the example above we see that the resulting tsvector does not contain the words a, on, or it, the word rats became rat, and the punctuation sign – was ignored.

The to_tsvector function internally calls a parser which breaks the document text into tokens and assigns a type to each token. For each token, a list of dictionaries (Section 12.6) is consulted, where the list can vary depending on the token type. The first dictionary that recognizes the token emits one or more normalized lexemes to represent the token. For example, rats became rat because one of the dictionaries recognized that the word rats is a plural form of rat. Some words are recognized as stop words (Section 12.6.1), which causes them to be ignored since they occur too frequently to be useful in searching. In our example these are a, on, and it. If no dictionary in the list recognizes the token then it is also ignored. In this example that happened to the punctuation sign – because there are in fact no dictionaries assigned for its token type (Space symbols), meaning space tokens will never be indexed. The choices of parser, dictionaries and which types of tokens to index are determined by the selected text search configuration (Section 12.7). It is possible to have many different configurations in the same database, and predefined configurations are available for various languages. In our example we used the default configuration english for the English language.

The function setweight can be used to label the entries of a tsvector with a given weight, where a weight is one of the letters A, B, C, or D. This is typically used to mark entries coming from different parts of a document, such as title versus body. Later, this information can be used for ranking of search results.

Because to_tsvector(NULL) will return NULL, it is recommended to use coalesce whenever a field might be null. Here is the recommended method for creating a tsvector from a structured document:

```sql
UPDATE tt SET ti =
  setweight(to_tsvector(coalesce(title,""), 'A') ||
  setweight(to_tsvector(coalesce(keyword,""), 'B') ||
  setweight(to_tsvector(coalesce(abstract,""), 'C') ||
  setweight(to_tsvector(coalesce(body,""), 'D');
```

Here we have used setweight to label the source of each lexeme in the finished tsvector, and then merged the labeled tsvector values using the tsvector concatenation operator ||. (Section 12.4.1 gives details about these operations.)

12.3.2. Parsing Queries

PostgreSQL provides the functions to_tsquery and plainto_tsquery for converting a query to the tsquery data type. to_tsquery offers access to more features than plainto_tsquery, but is less forgiving about its input.

```sql
to_tsquery([ config regconfig, ] querytext text) returns tsquery
```
to_tsquery creates a tsquery value from querytext, which must consist of single tokens separated by the Boolean operators \& (AND), | (OR) and ! (NOT). These operators can be grouped using parentheses. In other words, the input to to_tsquery must already follow the general rules for tsquery input, as described in Section 8.11. The difference is that while basic tsquery input takes the tokens at face value, to_tsquery normalizes each token to a lexeme using the specified or default configuration, and discards any tokens that are stop words according to the configuration. For example:

```sql
SELECT to_tsquery('english', 'The & Fat & Rats');
to_tsquery
-----------------
'fat' & 'rat'
```

As in basic tsquery input, weight(s) can be attached to each lexeme to restrict it to match only tsvector lexemes of those weight(s). For example:

```sql
SELECT to_tsquery('english', 'Fat | Rats:AB');
to_tsquery
-----------------
'fat' | 'rat':AB
```

to_tsquery can also accept single-quoted phrases. This is primarily useful when the configuration includes a thesaurus dictionary that may trigger on such phrases. In the example below, a thesaurus contains the rule supernovae stars : sn:

```sql
SELECT to_tsquery("'supernovae stars" & !crab");
to_tsquery
--------------
'sn' & '!crab'
```

Without quotes, to_tsquery will generate a syntax error for tokens that are not separated by an AND or OR operator.

```
plainto_tsquery([ config regconfig, ] querytext) returns tsquery
```

plainto_tsquery transforms unformatted text querytext to tsquery. The text is parsed and normalized much as for to_tsvector, then the & (AND) Boolean operator is inserted between surviving words.

Example:

```sql
SELECT plainto_tsquery('english', 'The Fat Rats');
plainto_tsquery
-----------------
'fat' & 'rat'
```

Note that plainto_tsquery cannot recognize either Boolean operators or weight labels in its input:

```sql
SELECT plaintexto_tsquery('english', 'The Fat & Rats:C');
plaintexto_tsquery
---------------------
'fat' & 'rat' & 'c'
```

Here, all the input punctuation was discarded as being space symbols.
12.3.3. Ranking Search Results

Ranking attempts to measure how relevant documents are to a particular query, so that when there are many matches the most relevant ones can be shown first. PostgreSQL provides two predefined ranking functions, which take into account lexical, proximity, and structural information; that is, they consider how often the query terms appear in the document, how close together the terms are in the document, and how important is the part of the document where they occur. However, the concept of relevancy is vague and very application-specific. Different applications might require additional information for ranking, e.g. document modification time. The built-in ranking functions are only examples. You can write your own ranking functions and/or combine their results with additional factors to fit your specific needs.

The two ranking functions currently available are:

\[ \text{ts\_rank}([ \text{weights float4}[]], \text{vector tsvector}, \text{query tsquery}, [, \text{normalization integer}]) \text{ returns float4} \]

Standard ranking function.

\[ \text{ts\_rank\_cd}([ \text{weights float4}[]], \text{vector tsvector}, \text{query tsquery}, [, \text{normalization integer}]) \text{ returns float4} \]

This function computes the cover density ranking for the given document vector and query, as described in Clarke, Cormack, and Tudhope’s "Relevance Ranking for One to Three Term Queries" in the journal "Information Processing and Management", 1999.

This function requires positional information in its input. Therefore it will not work on “stripped” tsvector values — it will always return zero.

For both these functions, the optional weights argument offers the ability to weigh word instances more or less heavily depending on how they are labeled. The weight arrays specify how heavily to weigh each category of word, in the order:

\{D-weight, C-weight, B-weight, A-weight\}

If no weights are provided, then these defaults are used:

\{0.1, 0.2, 0.4, 1.0\}

Typically weights are used to mark words from special areas of the document, like the title or an initial abstract, so that they can be treated as more or less important than words in the document body.

Since a longer document has a greater chance of containing a query term it is reasonable to take into account document size, e.g. a hundred-word document with five instances of a search word is probably more relevant than a thousand-word document with five instances. Both ranking functions take an integer normalization option that specifies whether and how a document’s length should impact its rank. The integer option controls several behaviors, so it is a bit mask: you can specify one or more behaviors using \text{\&} (for example, \text{2\&4}).

• 0 (the default) ignores the document length
• 1 divides the rank by \text{1 + the logarithm of the document length}
• 2 divides the rank by the document length
• 4 divides the rank by the mean harmonic distance between extents (this is implemented only by \text{ts\_rank\_cd})
• 8 divides the rank by the number of unique words in document
• 16 divides the rank by \text{1 + the logarithm of the number of unique words in document}
• 32 divides the rank by itself + 1

If more than one flag bit is specified, the transformations are applied in the order listed.

It is important to note that the ranking functions do not use any global information, so it is impossible to produce a fair normalization to 1% or 100% as sometimes desired. Normalization option 32 ($\text{rank}/(\text{rank}+1)$) can be applied to scale all ranks into the range zero to one, but of course this is just a cosmetic change; it will not affect the ordering of the search results.

Here is an example that selects only the ten highest-ranked matches:

```
SELECT title, ts_rank_cd(textsearch, query) AS rank
FROM apod, to_tsquery('neutrino|(dark & matter)') query
WHERE query @@ textsearch
ORDER BY rank DESC LIMIT 10;
```

```
title | rank
-----------------------------------------------+----------
Neutrinos in the Sun | 3.1
The Sudbury Neutrino Detector | 2.4
A MACHO View of Galactic Dark Matter | 2.01317
Hot Gas and Dark Matter | 1.91171
The Virgo Cluster: Hot Plasma and Dark Matter | 1.90953
Rafting for Solar Neutrinos | 1.9
NGC 4650A: Strange Galaxy and Dark Matter | 1.85774
Hot Gas and Dark Matter | 1.6123
Ice Fishing for Cosmic Neutrinos | 1.6
Weak Lensing Distorts the Universe | 0.818218
```

This is the same example using normalized ranking:

```
SELECT title, ts_rank_cd(textsearch, query, 32 /* rank/(rank+1) */ ) AS rank
FROM apod, to_tsquery('neutrino|(dark & matter)') query
WHERE query @@ textsearch
ORDER BY rank DESC LIMIT 10;
```

```
title | rank
-----------------------------------------------+-------------------
Neutrinos in the Sun | 0.756097569485493
The Sudbury Neutrino Detector | 0.705882361190954
A MACHO View of Galactic Dark Matter | 0.668123210574724
Hot Gas and Dark Matter | 0.6565958650282
The Virgo Cluster: Hot Plasma and Dark Matter | 0.656301290640973
Rafting for Solar Neutrinos | 0.655172410958162
NGC 4650A: Strange Galaxy and Dark Matter | 0.65072921219637
Hot Gas and Dark Matter | 0.617195790024749
Ice Fishing for Cosmic Neutrinos | 0.615384618911517
Weak Lensing Distorts the Universe | 0.450010798361481
```

Ranking can be expensive since it requires consulting the tsvector of each matching document, which can be I/O bound and therefore slow. Unfortunately, it is almost impossible to avoid since practical queries often result in large numbers of matches.
12.3.4. Highlighting Results

To present search results it is ideal to show a part of each document and how it is related to the query. Usually, search engines show fragments of the document with marked search terms. PostgreSQL provides a function `ts_headline` that implements this functionality.

```
SELECT ts_headline('english', 'The most common type of search is to find all documents containing given query terms and return them in order of their similarity to the query.', to_tsquery('query & similarity'));
```

The function `ts_headline` accepts a document along with a query, and returns an excerpt from the document in which terms from the query are highlighted. The configuration to be used to parse the document can be specified by `config`; if `config` is omitted, the `default_text_search_config` configuration is used.

If an `options` string is specified it must consist of a comma-separated list of one or more `option=value` pairs. The available options are:

- **StartSel, StopSel**: the strings with which query words appearing in the document should be delimited to distinguish them from other excerpted words.
- **MaxWords, MinWords**: these numbers determine the longest and shortest headlines to output.
- **ShortWord**: words of this length or less will be dropped at the start and end of a headline. The default value of three eliminates the English articles.
- **HighlightAll**: Boolean flag; if `true` the whole document will be highlighted.

Any unspecified options receive these defaults:

```
StartSel=<b>, StopSel=</b>, MaxWords=35, MinWords=15, ShortWord=3, HighlightAll=FALSE
```

For example:

```
SELECT ts_headline('english', 'The most common type of search is to find all documents containing given query terms and return them in order of their similarity to the query.', to_tsquery('query & similarity'));
```

```
SELECT ts_headline('english', 'The most common type of search is to find all documents containing given query terms and return them in order of their similarity to the query.', to_tsquery('query & similarity'), 'StartSel = <, StopSel = >');
```

```
SELECT ts_headline('english', 'The most common type of search is to find all documents containing given query terms and return them in order of their similarity to the query.', to_tsquery('query & similarity'), 'StartSel = <, StopSel = >');
```

```
SELECT ts_headline('english', 'The most common type of search is to find all documents containing given query terms and return them in order of their similarity to the query.', to_tsquery('query & similarity'), 'StartSel = <, StopSel = >');
```

```
SELECT ts_headline('english', 'The most common type of search is to find all documents containing given query terms and return them in order of their similarity to the query.', to_tsquery('query & similarity'), 'StartSel = <, StopSel = >');
```

Any unspecified options receive these defaults:

```
StartSel=<b>, StopSel=</b>, MaxWords=35, MinWords=15, ShortWord=3, HighlightAll=FALSE
```
ts_headline uses the original document, not a tsvector summary, so it can be slow and should be used with care. A typical mistake is to call ts_headline for every matching document when only ten documents are to be shown. SQL subqueries can help; here is an example:

```sql
SELECT id, ts_headline(body, q), rank
FROM (SELECT id, body, q, ts_rank_cd(ti, q) AS rank
     FROM apod, to_tsquery('stars') q
     WHERE ti @@ q
     ORDER BY rank DESC LIMIT 10) AS foo;
```

12.4. Additional Features

This section describes additional functions and operators that are useful in connection with text search.

12.4.1. Manipulating Documents

Section 12.3.1 showed how raw textual documents can be converted into tsvector values. PostgreSQL also provides functions and operators that can be used to manipulate documents that are already in tsvector form.

```
tsvector || tsvector
```

The tsvector concatenation operator returns a vector which combines the lexemes and positional information of the two vectors given as arguments. Positions and weight labels are retained during the concatenation. Positions appearing in the right-hand vector are offset by the largest position mentioned in the left-hand vector, so that the result is nearly equivalent to the result of performing to_tsvector on the concatenation of the two original document strings. (The equivalence is not exact, because any stop-words removed from the end of the left-hand argument will not affect the result, whereas they would have affected the positions of the lexemes in the right-hand argument if textual concatenation were used.)

One advantage of using concatenation in the vector form, rather than concatenating text before applying to_tsvector, is that you can use different configurations to parse different sections of the document. Also, because the setweight function marks all lexemes of the given vector the same way, it is necessary to parse the text and do setweight before concatenating if you want to label different parts of the document with different weights.

```
setweight(vector tsvector, weight "char") returns tsvector
```

This function returns a copy of the input vector in which every position has been labeled with the given weight, either A, B, C, or D. (D is the default for new vectors and as such is not displayed on output.) These labels are retained when vectors are concatenated, allowing words from different parts of a document to be weighted differently by ranking functions.

Note that weight labels apply to positions, not lexemes. If the input vector has been stripped of positions then setweight does nothing.
Chapter 12. Full Text Search

length(vector tsvector) returns integer

Returns the number of lexemes stored in the vector.

strip(vector tsvector) returns tsvector

Returns a vector which lists the same lexemes as the given vector, but which lacks any position or weight information. While the returned vector is much less useful than an unstripped vector for relevance ranking, it will usually be much smaller.

12.4.2. Manipulating Queries

Section 12.3.2 showed how raw textual queries can be converted into tsquery values. PostgreSQL also provides functions and operators that can be used to manipulate queries that are already in tsquery form.

\[\text{tsquery} \&\& \text{tsquery}\]

Returns the AND-combination of the two given queries.

\[\text{tsquery} || \text{tsquery}\]

Returns the OR-combination of the two given queries.

\[!! \text{tsquery}\]

Returns the negation (NOT) of the given query.

\[\text{numnode(query tsquery) returns integer}\]

Returns the number of nodes (lexemes plus operators) in a tsquery. This function is useful to determine if the query is meaningful (returns > 0), or contains only stop words (returns 0). Examples:

```sql
SELECT numnode(plainto_tsquery('the any'));
NOTICE: query contains only stopword(s) or doesn’t contain lexeme(s), ignored
numnode
---------
0
```

```sql
SELECT numnode('foo & bar':tsquery);
numnode
---------
3
```

\[\text{querytree(query tsquery) returns text}\]

Returns the portion of a tsquery that can be used for searching an index. This function is useful for detecting unindexable queries, for example those containing only stop words or only negated terms. For example:

```sql
SELECT querytree(to_tsquery('!defined'));
querytree
```
12.4.2.1. Query Rewriting

The ts_rewrite family of functions search a given tsquery for occurrences of a target subquery, and replace each occurrence with another substitute subquery. In essence this operation is a tsquery-specific version of substring replacement. A target and substitute combination can be thought of as a query rewrite rule. A collection of such rewrite rules can be a powerful search aid. For example, you can expand the search using synonyms (e.g., new york, big apple, nyc, gotham) or narrow the search to direct the user to some hot topic. There is some overlap in functionality between this feature and thesaurus dictionaries (Section 12.6.4). However, you can modify a set of rewrite rules on-the-fly without reindexing, whereas updating a thesaurus requires reindexing to be effective.

\[
\text{ts_rewrite (query tsquery, target tsquery, substitute tsquery) returns tsquery}
\]

This form of ts_rewrite simply applies a single rewrite rule: target is replaced by substitute wherever it appears in query. For example:

```
SELECT ts_rewrite('a & b'::tsquery, 'a'::tsquery, 'c'::tsquery);
```

\[
\text{ts_rewrite (query tsquery, select text) returns tsquery}
\]

This form of ts_rewrite accepts a starting query and a SQL select command, which is given as a text string. The select must yield two columns of tsquery type. For each row of the select result, occurrences of the first column value (the target) are replaced by the second column value (the substitute) within the current query value. For example:

```
CREATE TABLE aliases (t tsquery PRIMARY KEY, s tsquery);
INSERT INTO aliases VALUES('a', 'c');
SELECT ts_rewrite('a & b'::tsquery, 'SELECT t,s FROM aliases');
```

Note that when multiple rewrite rules are applied in this way, the order of application can be important; so in practice you will want the source query to ORDER BY some ordering key.

Let’s consider a real-life astronomical example. We’ll expand query supernovae using table-driven rewriting rules:

```
CREATE TABLE aliases (t tsquery primary key, s tsquery);
INSERT INTO aliases VALUES(to_tsquery('supernovae'), to_tsquery('supernovae|sn'));
SELECT ts_rewrite(to_tsquery('supernovae & crab'), 'SELECT * FROM aliases');
```

We can change the rewriting rules just by updating the table:

```
UPDATE aliases SET s = to_tsquery('supernovae|sn & !nebulae') WHERE t = to_tsquery('supernovae');
```
SELECT ts_rewrite(to_tquery('supernovae & crab'), 'SELECT * FROM aliases');

\texttt{ts_rewrite}

\begin{verbatim}
    'crab' \& \{ 'supernova' | 'sn' \& '!nebula' \}
\end{verbatim}

Rewriting can be slow when there are many rewriting rules, since it checks every rule for a possible hit. To filter out obvious non-candidate rules we can use the containment operators for the \texttt{tsquery} type. In the example below, we select only those rules which might match the original query:

\begin{verbatim}
SELECT ts_rewrite('a \& b':tsquery,
    'SELECT t,s FROM aliases WHERE "a \& b":tsquery @> t');
\end{verbatim}

\texttt{ts_rewrite}

\begin{verbatim}
    'b' \& 'c'
\end{verbatim}

### 12.4.3. Triggers for Automatic Updates

When using a separate column to store the \texttt{tsvector} representation of your documents, it is necessary to create a trigger to update the \texttt{tsvector} column when the document content columns change. Two built-in trigger functions are available for this, or you can write your own.

\begin{verbatim}
    tsvector_update_trigger(tsvector_column_name, config_name, text_column_name [, ... ])
    tsvector_update_trigger_column(tsvector_column_name, config_column_name, text_column_name)
\end{verbatim}

These trigger functions automatically compute a \texttt{tsvector} column from one or more textual columns, under the control of parameters specified in the \texttt{CREATE TRIGGER} command. An example of their use is:

\begin{verbatim}
CREATE TABLE messages {
    title     text,
    body      text,
    tsv         tsvector
};

CREATE TRIGGER tsvectorupdate BEFORE INSERT OR UPDATE
ON messages FOR EACH ROW EXECUTE PROCEDURE
    tsvector_update_trigger(tsv, 'pg\_catalog.english', title, body);

INSERT INTO messages VALUES('title here', 'the body text is here');

SELECT * FROM messages;

\begin{verbatim}
    title | body | tsv
    -----------------------------------------
    title here | the body text is here | 'bodi':4 'text':5 'titl':1
\end{verbatim}

SELECT title, body FROM messages WHERE tsv @@ to_tquery('title \& body');

\begin{verbatim}
    title | body
    -----------------------------------------
    title here | the body text is here
\end{verbatim}

265
Having created this trigger, any change in title or body will automatically be reflected into tsv, without the application having to worry about it.

The first trigger argument must be the name of the tsvector column to be updated. The second argument specifies the text search configuration to be used to perform the conversion. For tsvector_update_trigger, the configuration name is simply given as the second trigger argument. It must be schema-qualified as shown above, so that the trigger behavior will not change with changes in search_path. For tsvector_update_trigger_column, the second trigger argument is the name of another table column, which must be of type regconfig. This allows a per-row selection of configuration to be made. The remaining argument(s) are the names of textual columns (of type text, varchar, or char). These will be included in the document in the order given. NULL values will be skipped (but the other columns will still be indexed).

A limitation of the built-in triggers is that they treat all the input columns alike. To process columns differently — for example, to weight title differently from body — it is necessary to write a custom trigger. Here is an example using PL/pgSQL as the trigger language:

```
CREATE FUNCTION messages_trigger() RETURNS trigger AS $$
begin
    new.tsv :=
        setweight(to_tsvector('pg_catalog.english', coalesce(new.title,"")), 'A') ||
        setweight(to_tsvector('pg_catalog.english', coalesce(new.body,"")), 'D');
    return new;
end
$$ LANGUAGE plpgsql;

CREATE TRIGGER tsvectorupdate BEFORE INSERT OR UPDATE
ON messages FOR EACH ROW EXECUTE PROCEDURE messages_trigger();
```

Keep in mind that it is important to specify the configuration name explicitly when creating tsvector values inside triggers, so that the column’s contents will not be affected by changes to default_text_search_config. Failure to do this is likely to lead to problems such as search results changing after a dump and reload.

### 12.4.4. Gathering Document Statistics

The function ts_stat is useful for checking your configuration and for finding stop-word candidates.

```
ts_stat(sqlquery text, [ weights text, ] OUT word text, OUT ndoc integer, OUT nentry integer)
```

*sqlquery* is a text value containing a SQL query which must return a single tsvector column. ts_stat executes the query and returns statistics about each distinct lexeme (word) contained in the tsvector data. The columns returned are:

- **word text** — the value of a lexeme
- **ndoc integer** — number of documents (tsvectors) the word occurred in
- **nentry integer** — total number of occurrences of the word

If *weights* is supplied, only occurrences having one of those weights are counted.

For example, to find the ten most frequent words in a document collection:
12.5. Parsers

Text search parsers are responsible for splitting raw document text into tokens and identifying each token’s type, where the set of possible types is defined by the parser itself. Note that a parser does not modify the text at all — it simply identifies plausible word boundaries. Because of this limited scope, there is less need for application-specific custom parsers than there is for custom dictionaries.

At present PostgreSQL provides just one built-in parser, which has been found to be useful for a wide range of applications.

The built-in parser is named pg_catalog.default. It recognizes 23 token types:

<table>
<thead>

<td>File or path name</td>
<td>/usr/local/foo.txt, if not within a URL</td>
</tr>
</tbody>
</table>
Chapter 12. Full Text Search

<table>
<thead>
<tr>
<th>Alias</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>sfloat</td>
<td>Scientific notation</td>
<td>-1.234e56</td>
</tr>
<tr>
<td>float</td>
<td>Decimal notation</td>
<td>-1.234</td>
</tr>
<tr>
<td>int</td>
<td>Signed integer</td>
<td>-1234</td>
</tr>
<tr>
<td>uint</td>
<td>Unsigned integer</td>
<td>1234</td>
</tr>
<tr>
<td>version</td>
<td>Version number</td>
<td>8.3.0</td>
</tr>
<tr>
<td>tag</td>
<td>XML tag</td>
<td>&lt;a href=&quot;dictionaries.html&quot;&gt;</td>
</tr>
<tr>
<td>entity</td>
<td>XML entity</td>
<td>&amp;</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td>(any whitespace or punctuation not otherwise recognized)</td>
</tr>
</tbody>
</table>

Note: The parser’s notion of a “letter” is determined by the server’s locale setting, specifically lc_ctype. Words containing only the basic ASCII letters are reported as a separate token type, since it is sometimes useful to distinguish them. In most European languages, token types word and asciword should always be treated alike.

It is possible for the parser to produce overlapping tokens from the same piece of text. As an example, a hyphenated word will be reported both as the entire word and as each component:

```sql
SELECT alias, description, token FROM ts_debug('foo-bar-beta1');
```

<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
</tr>
</thead>
<tbody>
<tr>
<td>numhword</td>
<td>Hyphenated word, letters and digits</td>
<td>foo-bar-beta1</td>
</tr>
<tr>
<td>hword_asciipart</td>
<td>Hyphenated word part, all ASCII</td>
<td>foo</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td>-</td>
</tr>
<tr>
<td>hword_asciipart</td>
<td>Hyphenated word part, all ASCII</td>
<td>bar</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td>-</td>
</tr>
<tr>
<td>hword_numpart</td>
<td>Hyphenated word part, letters and digits</td>
<td>beta</td>
</tr>
</tbody>
</table>

This behavior is desirable since it allows searches to work for both the whole compound word and for components. Here is another instructive example:

```sql
SELECT alias, description, token FROM ts_debug('http://example.com/stuff/index.html');
```

<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
</tr>
</thead>
<tbody>
<tr>
<td>protocol</td>
<td>Protocol head</td>
<td>http://</td>
</tr>
<tr>
<td>url</td>
<td>URL</td>
<td>example.com/stuff/index.html</td>
</tr>
<tr>
<td>host</td>
<td>Host</td>
<td>example.com</td>
</tr>
<tr>
<td>url_path</td>
<td>URL path</td>
<td>/stuff/index.html</td>
</tr>
</tbody>
</table>

12.6. Dictionaries

Dictionaries are used to eliminate words that should not be considered in a search (stop words), and to normalize words so that different derived forms of the same word will match. A successfully normalized word is called a lexeme. Aside from improving search quality, normalization and removal of
stop words reduce the size of the tsvector representation of a document, thereby improving performance. Normalization does not always have linguistic meaning and usually depends on application semantics.

Some examples of normalization:

- Linguistic - Ispell dictionaries try to reduce input words to a normalized form; stemmer dictionaries remove word endings
- URL locations can be canonicalized to make equivalent URLs match:
  - http://www.pgsql.ru/db/mw/index.html
  - http://www.pgsql.ru/db/mw/
  - http://www.pgsql.ru/db/../db/mw/index.html
- Color names can be replaced by their hexadecimal values, e.g., red, green, blue, magenta -> FF0000, 00FF00, 0000FF, FF00FF
- If indexing numbers, we can remove some fractional digits to reduce the range of possible numbers, so for example 3.14159265359, 3.1415926, 3.14 will be the same after normalization if only two digits are kept after the decimal point.

A dictionary is a program that accepts a token as input and returns:

- an array of lexemes if the input token is known to the dictionary (notice that one token can produce more than one lexeme)
- an empty array if the dictionary knows the token, but it is a stop word
- NULL if the dictionary does not recognize the input token

PostgreSQL provides predefined dictionaries for many languages. There are also several predefined templates that can be used to create new dictionaries with custom parameters. Each predefined dictionary template is described below. If no existing template is suitable, it is possible to create new ones; see the contrib/ area of the PostgreSQL distribution for examples.

A text search configuration binds a parser together with a set of dictionaries to process the parser’s output tokens. For each token type that the parser can return, a separate list of dictionaries is specified by the configuration. When a token of that type is found by the parser, each dictionary in the list is consulted in turn, until some dictionary recognizes it as a known word. If it is identified as a stop word, or if no dictionary recognizes the token, it will be discarded and not indexed or searched for. The general rule for configuring a list of dictionaries is to place first the most narrow, most specific dictionary, then the more general dictionaries, finishing with a very general dictionary, like a Snowball stemmer or simple, which recognizes everything. For example, for an astronomy-specific search (astro_en configuration) one could bind token type asciiword (ASCII word) to a synonym dictionary of astronomical terms, a general English dictionary and a Snowball English stemmer:

```
ALTER TEXT SEARCH CONFIGURATION astro_en
    ADD MAPPING FOR asciiword WITH astrosyn, english_ispell, english_stem;
```

### 12.6.1. Stop Words

Stop words are words that are very common, appear in almost every document, and have no discrimination value. Therefore, they can be ignored in the context of full text searching. For example, every
English text contains words like a and the, so it is useless to store them in an index. However, stop words do affect the positions in tsvector, which in turn affect ranking:

```sql
SELECT to_tsvector('english','in the list of stop words');
```

```
'list':3 'stop':5 'word':6
```

The missing positions 1,2,4 are because of stop words. Ranks calculated for documents with and without stop words are quite different:

```sql
SELECT ts_rank_cd (to_tsvector('english','in the list of stop words'), to_tsquery('list & stop'));
```

```
ts_rank_cd
------------
0.05
```

```sql
SELECT ts_rank_cd (to_tsvector('english','list stop words'), to_tsquery('list & stop'));
```

```
ts_rank_cd
------------
0.1
```

It is up to the specific dictionary how it treats stop words. For example, ispell dictionaries first normalize words and then look at the list of stop words, while Snowball stemmers first check the list of stop words. The reason for the different behavior is an attempt to decrease noise.

### 12.6.2. Simple Dictionary

The simple dictionary template operates by converting the input token to lower case and checking it against a file of stop words. If it is found in the file then an empty array is returned, causing the token to be discarded. If not, the lower-cased form of the word is returned as the normalized lexeme. Alternatively, the dictionary can be configured to report non-stop-words as unrecognized, allowing them to be passed on to the next dictionary in the list.

Here is an example of a dictionary definition using the simple template:

```sql
CREATE TEXT SEARCH DICTIONARY public.simple_dict (
    TEMPLATE = pg_catalog.simple,
    STOPWORDS = english
);
```

Here, english is the base name of a file of stop words. The file’s full name will be $SHAREDIR/tsearch_data/english.stop, where $SHAREDIR means the PostgreSQL installation’s shared-data directory, often /usr/local/share/postgresql (use `pg_config --sharedir` to determine it if you’re not sure). The file format is simply a list of words, one per line. Blank lines and trailing spaces are ignored, and upper case is folded to lower case, but no other processing is done on the file contents.

Now we can test our dictionary:

```sql
SELECT ts_lexize('public.simple_dict','YeS');
```

```
ts_lexize
-----------
{yes}
```
We can also choose to return NULL, instead of the lower-cased word, if it is not found in the stop words file. This behavior is selected by setting the dictionary’s `Accept` parameter to false. Continuing the example:

```
ALTER TEXT SEARCH DICTIONARY public.simple_dict ( Accept = false );
```

```
SELECT ts_lexize('public.simple_dict','YeS');
```

```
SELECT ts_lexize('public.simple_dict','The');
```

With the default setting of `Accept = true`, it is only useful to place a simple dictionary at the end of a list of dictionaries, since it will never pass on any token to a following dictionary. Conversely, `Accept = false` is only useful when there is at least one following dictionary.

### Caution

Most types of dictionaries rely on configuration files, such as files of stop words. These files must be stored in UTF-8 encoding. They will be translated to the actual database encoding, if that is different, when they are read into the server.

### Caution

Normally, a database session will read a dictionary configuration file only once, when it is first used within the session. If you modify a configuration file and want to force existing sessions to pick up the new contents, issue an `ALTER TEXT SEARCH DICTIONARY` command on the dictionary. This can be a “dummy” update that doesn’t actually change any parameter values.

### 12.6.3. Synonym Dictionary

This dictionary template is used to create dictionaries that replace a word with a synonym. Phrases are not supported (use the thesaurus template (Section 12.6.4) for that). A synonym dictionary can be used to overcome linguistic problems, for example, to prevent an English stemmer dictionary from reducing the word ’Paris’ to ’pari’. It is enough to have a `Paris paris` line in the synonym dictionary and put it before the `english_stem` dictionary:

```
SELECT * FROM ts_debug('english', 'Paris');
```

```
<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
<th>dictionaries</th>
<th>dictionary</th>
<th>lexemes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```
Chapter 12. Full Text Search

CREATE TEXT SEARCH DICTIONARY my_synonym {
    TEMPLATE = synonym,
    SYNONYMS = my_synonyms
};

ALTER TEXT SEARCH CONFIGURATION english
    ALTER MAPPING FOR asciiword WITH my_synonym, english_stem;

SELECT * FROM ts_debug('english', 'Paris');

The only parameter required by the synonym template is SYNONYMS, which is the base name of its configuration file — my_synonyms in the above example. The file’s full name will be $SHAREDIR/tsearch_data/my_synonyms.syn (where $SHAREDIR means the PostgreSQL installation’s shared-data directory). The file format is just one line per word to be substituted, with the word followed by its synonym, separated by white space. Blank lines and trailing spaces are ignored, and upper case is folded to lower case.

12.6.4. Thesaurus Dictionary

A thesaurus dictionary (sometimes abbreviated as TZ) is a collection of words that includes information about the relationships of words and phrases, i.e., broader terms (BT), narrower terms (NT), preferred terms, non-preferred terms, related terms, etc.

Basically a thesaurus dictionary replaces all non-preferred terms by one preferred term and, optionally, preserves the original terms for indexing as well. PostgreSQL’s current implementation of the thesaurus dictionary is an extension of the synonym dictionary with added phrase support. A thesaurus dictionary requires a configuration file of the following format:

```
# this is a comment
sample word(s) : indexed word(s)
more sample word(s) : more indexed word(s)
...
```

where the colon (:) symbol acts as a delimiter between a a phrase and its replacement.

A thesaurus dictionary uses a subdictionary (which is specified in the dictionary’s configuration) to normalize the input text before checking for phrase matches. It is only possible to select one subdictionary. An error is reported if the subdictionary fails to recognize a word. In that case, you should remove the use of the word or teach the subdictionary about it. You can place an asterisk (*) at the beginning of an indexed word to skip applying the subdictionary to it, but all sample words must be known to the subdictionary.

The thesaurus dictionary chooses the longest match if there are multiple phrases matching the input, and ties are broken by using the last definition.

Specific stop words recognized by the subdictionary cannot be specified; instead use ? to mark the location where any stop word can appear. For example, assuming that a and the are stop words according to the subdictionary:
matches a one the two and the one a two; both would be replaced by swsw.

Since a thesaurus dictionary has the capability to recognize phrases it must remember its state and interact with the parser. A thesaurus dictionary uses these assignments to check if it should handle the next word or stop accumulation. The thesaurus dictionary must be configured carefully. For example, if the thesaurus dictionary is assigned to handle only the asciiword token, then a thesaurus dictionary definition like one 7 will not work since token type uint is not assigned to the thesaurus dictionary.

**Caution**

Thesauruses are used during indexing so any change in the thesaurus dictionary's parameters requires reindexing. For most other dictionary types, small changes such as adding or removing stopwords does not force reindexing.

### 12.6.4.1. Thesaurus Configuration

To define a new thesaurus dictionary, use the *thesaurus* template. For example:

```sql
CREATE TEXT SEARCH DICTIONARY thesaurus_simple (  
    TEMPLATE = thesaurus,  
    DictFile = mythesaurus,  
    Dictionary = pg_catalog.english_stem
);
```

Here:

- `thesaurus_simple` is the new dictionary's name
- `mythesaurus` is the base name of the thesaurus configuration file. (Its full name will be `$SHAREDIR/tsearch_data/mythesaurus.ths`, where `$SHAREDIR` means the installation shared-data directory.)
- `pg_catalog.english_stem` is the subdictionary (here, a Snowball English stemmer) to use for thesaurus normalization. Notice that the subdictionary will have its own configuration (for example, stop words), which is not shown here.

Now it is possible to bind the thesaurus dictionary `thesaurus_simple` to the desired token types in a configuration, for example:

```sql
ALTER TEXT SEARCH CONFIGURATION russian  
    ALTER MAPPING FOR asciiword, asciihword, hword_asciipart WITH thesaurus_simple;
```

### 12.6.4.2. Thesaurus Example

Consider a simple astronomical thesaurus `thesaurus_astro`, which contains some astronomical word combinations:

- supernovae stars : sn
- crab nebulae : crab
Below we create a dictionary and bind some token types to an astronomical thesaurus and English stemmer:

```sql
CREATE TEXT SEARCH DICTIONARY thesaurus_astro (  
    TEMPLATE = thesaurus,  
    DictFile = thesaurus_astro,  
    Dictionary = english_stem
);
```

ALTER TEXT SEARCH CONFIGURATION russian
ALTER MAPPING FOR asciiword, asciihword, hword_asciipart WITH thesaurus_astro, english_stem;

Now we can see how it works. `ts_lexize` is not very useful for testing a thesaurus, because it treats its input as a single token. Instead we can use `plainto_tsquery` and `to_tsvector` which will break their input strings into multiple tokens:

```sql
SELECT plainto_tsquery('supernova star');
plainto_tsquery
-----------------
'sn'

SELECT to_tsvector('supernova star');
to_tsvector
-----------------
'sn':1
```

In principle, one can use `to_tsquery` if you quote the argument:

```sql
SELECT to_tsquery('"supernova star"');
to_tsquery
-----------------
'sn'
```

Notice that `supernova star` matches `supernovae stars` in `thesaurus_astro` because we specified the `english_stem` stemmer in the thesaurus definition. The stemmer removed the `e` and `s`.

To index the original phrase as well as the substitute, just include it in the right-hand part of the definition:

```sql
supernovae stars : sn supernovae stars
```

```sql
SELECT plainto_tsquery('supernova star');
plainto_tsquery
-----------------------------
'sn' & 'supernova' & 'star'
```

### 12.6.5. Ispell Dictionary

The Ispell dictionary template supports morphological dictionaries, which can normalize many different linguistic forms of a word into the same lexeme. For example, an English Ispell dictionary can match all declensions and conjugations of the search term `bank`, e.g. `banking`, `banked`, `banks`, `banks'`, and `bank’s`. 

274
The standard PostgreSQL distribution does not include any Ispell configuration files. Dictionaries for a large number of languages are available from Ispell\(^1\). Also, some more modern dictionary file formats are supported — MySpell\(^2\) (OO < 2.0.1) and Hunspell\(^3\) (OO \(\geq\) 2.0.2). A large list of dictionaries is available on the OpenOffice Wiki\(^4\).

To create an Ispell dictionary, use the built-in `ispell` template and specify several parameters:

```sql
CREATE TEXT SEARCH DICTIONARY english_ispell (
  TEMPLATE = ispell,
  DictFile = english,
  AffFile = english,
  StopWords = english
);
```

Here, `DictFile`, `AffFile`, and `StopWords` specify the base names of the dictionary, affixes, and stop-words files. The stop-words file has the same format explained above for the simple dictionary type. The format of the other files is not specified here but is available from the above-mentioned web sites.

Ispell dictionaries usually recognize a limited set of words, so they should be followed by another broader dictionary, for example, a Snowball dictionary, which recognizes everything.

Ispell dictionaries support splitting compound words. This is a nice feature and PostgreSQL supports it. Notice that the affix file should specify a special flag using the `compoundwords controlled` statement that marks dictionary words that can participate in compound formation:

```sql
compoundwords controlled z
```

Here are some examples for the Norwegian language:

```sql
SELECT ts_lexize('norwegian_ispell', 'overbuljongterningpakkmesterassistent');
{over,buljong,terning,pakk,mester,assistent}
SELECT ts_lexize('norwegian_ispell', 'sjokoladefabrikk');
{sjokoladefabrikk,sjokolade,fabrikk}
```

**Note:** MySpell does not support compound words. Hunspell has sophisticated support for compound words. At present, PostgreSQL implements only the basic compound word operations of Hunspell.

### 12.6.6. Snowball Dictionary

The Snowball dictionary template is based on the project of Martin Porter, inventor of the popular Porter’s stemming algorithm for the English language. Snowball now provides stemming algorithms for many languages (see the Snowball site\(^5\) for more information). Each algorithm understands how to reduce common variant forms of words to a base, or stem, spelling within its language. A Snowball dictionary requires a `language` parameter to identify which stemmer to use, and optionally can specify a `stopword` file name that gives a list of words to eliminate. (PostgreSQL’s standard stopword

---

lists are also provided by the Snowball project.) For example, there is a built-in definition equivalent to

```sql
CREATE TEXT SEARCH DICTIONARY english_stem {
    TEMPLATE = snowball,
    Language = english,
    StopWords = english
};
```

The stopword file format is the same as already explained. A Snowball dictionary recognizes everything, whether or not it is able to simplify the word, so it should be placed at the end of the dictionary list. It is useless to have it before any other dictionary because a token will never pass through it to the next dictionary.

### 12.7. Configuration Example

A text search configuration specifies all options necessary to transform a document into a `tsvector`: the parser to use to break text into tokens, and the dictionaries to use to transform each token into a lexeme. Every call of `to_tsvector` or `to_tsquery` needs a text search configuration to perform its processing. The configuration parameter `default_text_search_config` specifies the name of the default configuration, which is the one used by text search functions if an explicit configuration parameter is omitted. It can be set in `postgresql.conf`, or set for an individual session using the `SET` command.

Several predefined text search configurations are available, and you can create custom configurations easily. To facilitate management of text search objects, a set of SQL commands is available, and there are several `psql` commands that display information about text search objects (Section 12.10).

As an example, we will create a configuration `pg`, starting from a duplicate of the built-in `english` configuration.

```sql
CREATE TEXT SEARCH CONFIGURATION public.pg ( COPY = pg_catalog.english );
```

We will use a PostgreSQL-specific synonym list and store it in `$SHAREDIR/tsearch_data/pg_dict.syn`. The file contents look like:

```
postgres pg
pgsql pg
postgresql pg
```

We define the synonym dictionary like this:

```sql
CREATE TEXT SEARCH DICTIONARY pg_dict {
    TEMPLATE = synonym,
    SYNONYMS = pg_dict
};
```

Next we register the Ispell dictionary `english_ispell`, which has its own configuration files:

```sql
CREATE TEXT SEARCH DICTIONARY english_ispell {
    TEMPLATE = ispell,
    DictFile = english,
    AffFile = english,
    StopWords = english
};
```
Now we can set up the mappings for words in configuration pg:

```sql
ALTER TEXT SEARCH CONFIGURATION pg
    ALTER MAPPING FOR asciiword, asciihword, hword_asciipart, word, hword, hword_part
    WITH pg_dict, english_ispell, english_stem;
```

We choose not to index or search some token types that the built-in configuration does handle:

```sql
ALTER TEXT SEARCH CONFIGURATION pg
    DROP MAPPING FOR email, url, url_path, sfloat, float;
```

Now we can test our configuration:

```sql
SELECT * FROM ts_debug('public.pg', 'PostgreSQL, the highly scalable, SQL compliant, open source object-relational database management system, is now undergoing beta testing of the next version of our software. ');
```

The next step is to set the session to use the new configuration, which was created in the public schema:

```sql
=> \dF
   List of text search configurations
   Schema    | Name | Description
   ---------+------|----------------
   public   | pg   |

SET default_text_search_config = 'public.pg';
SET SHOW default_text_search_config;
default_text_search_config
-----------------------------
public.pg
```

12.8. Testing and Debugging Text Search

The behavior of a custom text search configuration can easily become complicated enough to be confusing or undesirable. The functions described in this section are useful for testing text search objects. You can test a complete configuration, or test parsers and dictionaries separately.
12.8.1. Configuration Testing

The function `ts_debug` allows easy testing of a text search configuration.

```sql
ts_debug([ config regconfig, ] document text,
   OUT alias text,
   OUT description text,
   OUT token text,
   OUT dictionaries regdictionary[],
   OUT dictionary regdictionary,
   OUT lexemes text[])
returns setof record
```

`ts_debug` displays information about every token of `document` as produced by the parser and processed by the configured dictionaries. It uses the configuration specified by `config`, or `default_text_search_config` if that argument is omitted.

`ts_debug` returns one row for each token identified in the text by the parser. The columns returned are

- `alias text` — short name of the token type
- `description text` — description of the token type
- `token text` — text of the token
- `dictionaries regdictionary[]` — the dictionaries selected by the configuration for this token type
- `dictionary regdictionary` — the dictionary that recognized the token, or NULL if none did
- `lexemes text[]` — the lexeme(s) produced by the dictionary that recognized the token, or NULL if none did; an empty array (``) means it was recognized as a stop word

Here is a simple example:

```sql
SELECT * FROM ts_debug('english','a fat cat sat on a mat - it ate a fat rats');
```

<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
<th>dictionaries</th>
<th>dictionary</th>
<th>lexemes</th>
</tr>
</thead>
<tbody>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>a</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>

<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>mat</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{mat}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>it</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>ate</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{ate}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>a</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
For a more extensive demonstration, we first create a public.english configuration and Ispell dictionary for the English language:

CREATE TEXT SEARCH CONFIGURATION public.english ( COPY = pg_catalog.english );

CREATE TEXT SEARCH DICTIONARY english_ispell {
    TEMPLATE = ispell,
    DictFile = english,
    AffFile = english,
    StopWords = english
};

ALTER TEXT SEARCH CONFIGURATION public.english
ALTER MAPPING FOR asciiword WITH english_ispell, english_stem;

SELECT * FROM ts_debug('public.english','The Brightest supernovaes');

<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
<th>dictionaries</th>
<th>dictionary</th>
</tr>
</thead>
<tbody>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>The</td>
<td>{english_ispell,english_stem}</td>
<td>english_ispell</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>()</td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>Brightest</td>
<td>{english_ispell,english_stem}</td>
<td>english_ispell</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>()</td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>supernovaes</td>
<td>{english_ispell,english_stem}</td>
<td>english_stem</td>
</tr>
</tbody>
</table>

In this example, the word **Brightest** was recognized by the parser as an ASCII word (alias asciiword). For this token type the dictionary list is english_ispell and english_stem. The word was recognized by english_ispell, which reduced it to the noun **bright**. The word supernovaes is unknown to the english_ispell dictionary so it was passed to the next dictionary, and, fortunately, was recognized (in fact, english_stem is a Snowball dictionary which recognizes everything; that is why it was placed at the end of the dictionary list).

The word **The** was recognized by the english_ispell dictionary as a stop word (Section 12.6.1) and will not be indexed. The spaces are discarded too, since the configuration provides no dictionaries at all for them.

You can reduce the volume of output by explicitly specifying which columns you want to see:

SELECT alias, token, dictionary, lexemes
FROM ts_debug('public.english','The Brightest supernovaes');

<table>
<thead>
<tr>
<th>alias</th>
<th>token</th>
<th>dictionary</th>
<th>lexemes</th>
</tr>
</thead>
<tbody>
<tr>
<td>asciiword</td>
<td>The</td>
<td>english_ispell</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Brightest</td>
<td>english_ispell</td>
<td>{bright}</td>
</tr>
<tr>
<td>blank</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>supernovaes</td>
<td>english_stem</td>
<td>{supernova}</td>
</tr>
</tbody>
</table>

279
12.8.2. Parser Testing

The following functions allow direct testing of a text search parser.

```sql
ts_parse(parser_name text, document text, OUT tokid integer, OUT token text) returns setof record
```

```sql
ts_parse(parser_oid oid, document text, OUT tokid integer, OUT token text) returns setof record
```

`ts_parse` parses the given `document` and returns a series of records, one for each token produced by parsing. Each record includes a `tokid` showing the assigned token type and a `token` which is the text of the token. For example:

```sql
SELECT * FROM ts_parse('default', '123 - a number');
```

<table>
<thead>
<tr>
<th>tokid</th>
<th>token</th>
</tr>
</thead>
<tbody>
<tr>
<td>22</td>
<td>123</td>
</tr>
<tr>
<td>12</td>
<td>-</td>
</tr>
<tr>
<td>1</td>
<td>a</td>
</tr>
<tr>
<td>12</td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>number</td>
</tr>
</tbody>
</table>

```sql
```

```sql
```

```sql
```

```sql
```

```sql
```

```sql
```

```sql
```

```sql
```
12.8.3. Dictionary Testing

The `ts_lexize` function facilitates dictionary testing.

\[ \text{ts_lexize}(\text{dict \ regdictionary, token text}) \text{ returns text[]} \]

`ts_lexize` returns an array of lexemes if the input `token` is known to the dictionary, or an empty array if the token is known to the dictionary but it is a stop word, or `NULL` if it is an unknown word.

Examples:

```sql
SELECT ts_lexize('english_stem', 'stars');
```

```
{star}
```

```sql
SELECT ts_lexize('english_stem', 'a');
```

```
{}
```

**Note:** The `ts_lexize` function expects a single `token`, not text. Here is a case where this can be confusing:

```sql
SELECT ts_lexize('thesaurus_astro','supernovae stars') is null;
```

```
t
```

The thesaurus dictionary `thesaurus_astro` does know the phrase `supernovae stars`, but `ts_lexize` fails since it does not parse the input text but treats it as a single token. Use `plainto_tsquery` or `to_tsvector` to test thesaurus dictionaries, for example:

```sql
SELECT plainto_tsquery('supernovae stars');
```

```
'sn'
```
12.9. GiST and GIN Index Types

There are two kinds of indexes that can be used to speed up full text searches. Note that indexes are not mandatory for full text searching, but in cases where a column is searched on a regular basis, an index will usually be desirable.

```
CREATE INDEX name ON table USING gist(column);
```

Creates a GiST (Generalized Search Tree)-based index. The column can be of tsvector or tsquery type.

```
CREATE INDEX name ON table USING gin(column);
```

Creates a GIN (Generalized Inverted Index)-based index. The column must be of tsvector type.

There are substantial performance differences between the two index types, so it is important to understand which to use.

A GiST index is lossy, meaning that the index may produce false matches, and it is necessary to check the actual table row to eliminate such false matches. PostgreSQL does this automatically; for example, in the query plan below, the Filter: line indicates the index output will be rechecked:

```
EXPLAIN SELECT * FROM apod WHERE textsearch @@ to_tsquery('supernovae');
```

```
QUERY PLAN
-------------------------------------------------------------------------
Index Scan using textsearch_gidx on apod (cost=0.00..12.29 rows=2 width=1469)
  Index Cond: (textsearch @@ to_tsquery('supernovae'))
  Filter: (textsearch @@ to_tsquery('supernovae'))
-------------------------------------------------------------------------
```

GiST indexes are lossy because each document is represented in the index by a fixed-length signature. The signature is generated by hashing each word into a random bit in an n-bit string, with all these bits OR-ed together to produce an n-bit document signature. When two words hash to the same bit position there will be a false match. If all words in the query have matches (real or false) then the table row must be retrieved to see if the match is correct.

Lossiness causes performance degradation due to useless fetches of table records that turn out to be false matches. Since random access to table records is slow, this limits the usefulness of GiST indexes. The likelihood of false matches depends on several factors, in particular the number of unique words, so using dictionaries to reduce this number is recommended.

GIN indexes are not lossy but their performance depends logarithmically on the number of unique words.

Actually, GIN indexes store only the words (lexemes) of tsvector values, and not their weight labels. Thus, while a GIN index can be considered non-lossy for a query that does not specify weights, it is lossy for one that does. Thus a table row recheck is needed when using a query that involves weights. Unfortunately, in the current design of PostgreSQL, whether a recheck is needed is a static property of a particular operator, and not something that can be enabled or disabled on-the-fly depending on the values given to the operator. To deal with this situation without imposing the overhead of rechecks on queries that do not need them, the following approach has been adopted:

- The standard text match operator @@ is marked as non-lossy for GIN indexes.
• An additional match operator @@@ is provided, and marked as lossy for GIN indexes. This operator behaves exactly like @@ otherwise.
• When a GIN index search is initiated with the @@ operator, the index support code will throw an error if the query specifies any weights. This protects against giving wrong answers due to failure to recheck the weights.

In short, you must use @@@ rather than @@ to perform GIN index searches on queries that involve weight restrictions. For queries that do not have weight restrictions, either operator will work, but @@ will be faster. This awkwardness will probably be addressed in a future release of PostgreSQL.

In choosing which index type to use, GiST or GIN, consider these performance differences:

• GIN index lookups are about three times faster than GiST
• GIN indexes take about three times longer to build than GiST
• GIN indexes are about ten times slower to update than GiST
• GIN indexes are two-to-three times larger than GiST

As a rule of thumb, GIN indexes are best for static data because lookups are faster. For dynamic data, GiST indexes are faster to update. Specifically, GiST indexes are very good for dynamic data and fast if the number of unique words (lexemes) is under 100,000, while GIN indexes will handle 100,000+ lexemes better but are slower to update.

Note that GIN index build time can often be improved by increasing maintenance_work_mem, while GiST index build time is not sensitive to that parameter.

Partitioning of big collections and the proper use of GiST and GIN indexes allows the implementation of very fast searches with online update. Partitioning can be done at the database level using table inheritance and constraint_exclusion, or by distributing documents over servers and collecting search results using the contrib/dblink extension module. The latter is possible because ranking functions use only local information.

12.10. psql Support

Information about text search configuration objects can be obtained in psql using a set of commands:

```
\dF{d,p,t} [+][PATTERN]
```

An optional + produces more details.

The optional parameter PATTERN should be the name of a text search object, optionally schema-qualified. If PATTERN is omitted then information about all visible objects will be displayed. PATTERN can be a regular expression and can provide separate patterns for the schema and object names. The following examples illustrate this:

```
=> \dF *fulltext*
  List of text search configurations
  Schema | Name            | Description
  --------+------------------+------------------
  public  | fulltext_cfg     |                 

=> \dF *.fulltext*
  List of text search configurations
  Schema | Name            | Description
```

283

### 12.11. Limitations

The current limitations of PostgreSQL’s text search features are:

- The length of each lexeme must be less than 2K bytes
- The length of a `tsvector` (lexemes + positions) must be less than 1 megabyte
- The number of lexemes must be less than $2^{64}$
- Position values in `tsvector` must be greater than 0 and no more than 16,383
- No more than 256 positions per lexeme
- The number of nodes (lexemes + operators) in a `tsquery` must be less than 32,768

For comparison, the PostgreSQL 8.1 documentation contained 10,441 unique words, a total of 335,420 words, and the most frequent word “postgresql” was mentioned 6,127 times in 655 documents.

Another example — the PostgreSQL mailing list archives contained 910,989 unique words with 57,491,343 lexemes in 461,020 messages.

### 12.12. Migration from Pre-8.3 Text Search

Applications that used the `contrib/tsearch2` add-on module for text searching will need some adjustments to work with the built-in features:

- Some functions have been renamed or had small adjustments in their argument lists, and all of them are now in the `pg_catalog` schema, whereas in a previous installation they would have been in `public` or another non-system schema. There is a new version of `contrib/tsearch2` (see Section F.31) that provides a compatibility layer to solve most problems in this area.
- The old `contrib/tsearch2` functions and other objects must be suppressed when loading `pg_dump` output from a pre-8.3 database. While many of them won’t load anyway, a few will and then cause problems. One simple way to deal with this is to load the new `contrib/tsearch2` module before restoring the dump; then it will block the old objects from being loaded.
- Text search configuration setup is completely different now. Instead of manually inserting rows into configuration tables, search is configured through the specialized SQL commands shown earlier.
in this chapter. There is not currently any automated support for converting an existing custom configuration for 8.3; you’re on your own here.

- Most types of dictionaries rely on some outside-the-database configuration files. These are largely compatible with pre-8.3 usage, but note the following differences:
  - Configuration files now must be placed in a single specified directory (\$SHAREDIR/tsearch_data), and must have a specific extension depending on the type of file, as noted previously in the descriptions of the various dictionary types. This restriction was added to forestall security problems.
  - Configuration files must be encoded in UTF-8 encoding, regardless of what database encoding is used.
  - In thesaurus configuration files, stop words must be marked with?.
Chapter 13. Concurrency Control

This chapter describes the behavior of the PostgreSQL database system when two or more sessions try to access the same data at the same time. The goals in that situation are to allow efficient access for all sessions while maintaining strict data integrity. Every developer of database applications should be familiar with the topics covered in this chapter.

13.1. Introduction

PostgreSQL provides a rich set of tools for developers to manage concurrent access to data. Internally, data consistency is maintained by using a multiversion model (Multiversion Concurrency Control, MVCC). This means that while querying a database each transaction sees a snapshot of data (a database version) as it was some time ago, regardless of the current state of the underlying data. This protects the transaction from viewing inconsistent data that could be caused by (other) concurrent transaction updates on the same data rows, providing transaction isolation for each database session. MVCC, by eschewing explicit locking methodologies of traditional database systems, minimizes lock contention in order to allow for reasonable performance in multiuser environments.

The main advantage to using the MVCC model of concurrency control rather than locking is that in MVCC locks acquired for querying (reading) data do not conflict with locks acquired for writing data, and so reading never blocks writing and writing never blocks reading.

Table- and row-level locking facilities are also available in PostgreSQL for applications that cannot adapt easily to MVCC behavior. However, proper use of MVCC will generally provide better performance than locks. In addition, application-defined advisory locks provide a mechanism for acquiring locks that are not tied to a single transaction.

13.2. Transaction Isolation

The SQL standard defines four levels of transaction isolation in terms of three phenomena that must be prevented between concurrent transactions. These undesirable phenomena are:

- **dirty read**
  A transaction reads data written by a concurrent uncommitted transaction.

- **nonrepeatable read**
  A transaction re-reads data it has previously read and finds that data has been modified by another transaction (that committed since the initial read).

- **phantom read**
  A transaction re-executes a query returning a set of rows that satisfy a search condition and finds that the set of rows satisfying the condition has changed due to another recently-committed transaction.

The four transaction isolation levels and the corresponding behaviors are described in Table 13-1.

Table 13-1. SQL Transaction Isolation Levels
Chapter 13. Concurrency Control

<table>
<thead>
<tr>
<th>Isolation Level</th>
<th>Dirty Read</th>
<th>Nonrepeatable Read</th>
<th>Phantom Read</th>
</tr>
</thead>
<tbody>
<tr>

<tr>
<td>Repeatable read</td>
<td>Not possible</td>
<td>Not possible</td>
<td>Possible</td>
</tr>
<tr>
<td>Serializable</td>
<td>Not possible</td>
<td>Not possible</td>
<td>Not possible</td>
</tr>
</tbody>
</table>

In PostgreSQL, you can request any of the four standard transaction isolation levels. But internally, there are only two distinct isolation levels, which correspond to the levels Read Committed and Serializable. When you select the level Read Uncommitted you really get Read Committed, and when you select Repeatable Read you really get Serializable, so the actual isolation level might be stricter than what you select. This is permitted by the SQL standard: the four isolation levels only define which phenomena must not happen, they do not define which phenomena must happen. The reason that PostgreSQL only provides two isolation levels is that this is the only sensible way to map the standard isolation levels to the multiversion concurrency control architecture. The behavior of the available isolation levels is detailed in the following subsections.

To set the transaction isolation level of a transaction, use the command `SET TRANSACTION`.

13.2.1. Read Committed Isolation Level

*Read Committed* is the default isolation level in PostgreSQL. When a transaction runs on this isolation level, a `SELECT` query sees only data committed before the query began; it never sees either uncommitted data or changes committed during query execution by concurrent transactions. (However, the `SELECT` does see the effects of previous updates executed within its own transaction, even though they are not yet committed.) In effect, a `SELECT` query sees a snapshot of the database as of the instant that that query begins to run. Notice that two successive `SELECT` commands can see different data, even though they are within a single transaction, if other transactions commit changes during execution of the first `SELECT`.

`UPDATE`, `DELETE`, `SELECT FOR UPDATE`, and `SELECT FOR SHARE` commands behave the same as `SELECT` in terms of searching for target rows: they will only find target rows that were committed as of the command start time. However, such a target row might have already been updated (or deleted or locked) by another concurrent transaction by the time it is found. In this case, the would-be updaters will wait for the first updating transaction to commit or roll back (if it is still in progress). If the first updater rolls back, then its effects are negated and the second updater can proceed with updating the originally found row. If the first updater commits, the second updater will ignore the row if the first updater deleted it, otherwise it will attempt to apply its operation to the updated version of the row. The search condition of the command (the `WHERE` clause) is re-evaluated to see if the updated version of the row still matches the search condition. If so, the second updater proceeds with its operation, starting from the updated version of the row. (In the case of `SELECT FOR UPDATE` and `SELECT FOR SHARE`, that means it is the updated version of the row that is locked and returned to the client.)

Because of the above rule, it is possible for an updating command to see an inconsistent snapshot: it can see the effects of concurrent updating commands that affected the same rows it is trying to update, but it does not see effects of those commands on other rows in the database. This behavior makes Read Committed mode unsuitable for commands that involve complex search conditions. However, it is just right for simpler cases. For example, consider updating bank balances with transactions like

```
BEGIN;
UPDATE accounts SET balance = balance + 100.00 WHERE acctnum = 12345;
UPDATE accounts SET balance = balance - 100.00 WHERE acctnum = 7534;
COMMIT;
```
Chapter 13. Concurrency Control

If two such transactions concurrently try to change the balance of account 12345, we clearly want the second transaction to start from the updated version of the account’s row. Because each command is affecting only a predetermined row, letting it see the updated version of the row does not create any troublesome inconsistency.

Since in Read Committed mode each new command starts with a new snapshot that includes all transactions committed up to that instant, subsequent commands in the same transaction will see the effects of the committed concurrent transaction in any case. The point at issue here is whether or not within a single command we see an absolutely consistent view of the database.

The partial transaction isolation provided by Read Committed mode is adequate for many applications, and this mode is fast and simple to use. However, for applications that do complex queries and updates, it might be necessary to guarantee a more rigorously consistent view of the database than the Read Committed mode provides.

13.2.2. Serializable Isolation Level

The level Serializable provides the strictest transaction isolation. This level emulates serial transaction execution, as if transactions had been executed one after another, serially, rather than concurrently. However, applications using this level must be prepared to retry transactions due to serialization failures.

When a transaction is on the serializable level, a SELECT query sees only data committed before the transaction began; it never sees either uncommitted data or changes committed during transaction execution by concurrent transactions. (However, the SELECT does see the effects of previous updates executed within its own transaction, even though they are not yet committed.) This is different from Read Committed in that the SELECT sees a snapshot as of the start of the transaction, not as of the start of the current query within the transaction. Thus, successive SELECT commands within a single transaction always see the same data.

UPDATE, DELETE, SELECT FOR UPDATE, and SELECT FOR SHARE commands behave the same as SELECT in terms of searching for target rows: they will only find target rows that were committed as of the transaction start time. However, such a target row might have already been updated (or deleted or locked) by another concurrent transaction by the time it is found. In this case, the serializable transaction will wait for the first updating transaction to commit or roll back (if it is still in progress). If the first updater rolls back, then its effects are negated and the serializable transaction can proceed with updating the originally found row. But if the first updater commits (and actually updated or deleted the row, not just locked it) then the serializable transaction will be rolled back with the message

ERROR: could not serialize access due to concurrent update

because a serializable transaction cannot modify or lock rows changed by other transactions after the serializable transaction began.

When the application receives this error message, it should abort the current transaction and then retry the whole transaction from the beginning. The second time through, the transaction sees the previously-committed change as part of its initial view of the database, so there is no logical conflict in using the new version of the row as the starting point for the new transaction’s update.

Note that only updating transactions might need to be retried; read-only transactions will never have serialization conflicts.

The Serializable mode provides a rigorous guarantee that each transaction sees a wholly consistent view of the database. However, the application has to be prepared to retry transactions when concurrent updates make it impossible to sustain the illusion of serial execution. Since the cost of redoing
complex transactions might be significant, this mode is recommended only when updating transactions contain logic sufficiently complex that they might give wrong answers in Read Committed mode. Most commonly, Serializable mode is necessary when a transaction executes several successive commands that must see identical views of the database.

### 13.2.2.1. Serializable Isolation versus True Serializability

The intuitive meaning (and mathematical definition) of “serializable” execution is that any two successfully committed concurrent transactions will appear to have executed strictly serially, one after the other — although which one appeared to occur first might not be predictable in advance. It is important to realize that forbidding the undesirable behaviors listed in Table 13-1 is not sufficient to guarantee true serializability, and in fact PostgreSQL’s Serializable mode does not guarantee serializable execution in this sense. As an example, consider a table `mytab`, initially containing

<table>
<thead>
<tr>
<th>class</th>
<th>value</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>10</td>
</tr>
<tr>
<td>1</td>
<td>20</td>
</tr>
<tr>
<td>2</td>
<td>100</td>
</tr>
<tr>
<td>2</td>
<td>200</td>
</tr>
</tbody>
</table>

Suppose that serializable transaction A computes

```sql
SELECT SUM(value) FROM mytab WHERE class = 1;
```

and then inserts the result (30) as the value in a new row with `class = 2`. Concurrently, serializable transaction B computes

```sql
SELECT SUM(value) FROM mytab WHERE class = 2;
```

and obtains the result 300, which it inserts in a new row with `class = 1`. Then both transactions commit. None of the listed undesirable behaviors have occurred, yet we have a result that could not have occurred in either order serially. If A had executed before B, B would have computed the sum 330, not 300, and similarly the other order would have resulted in a different sum computed by A.

To guarantee true mathematical serializability, it is necessary for a database system to enforce predicate locking, which means that a transaction cannot insert or modify a row that would have matched the `WHERE` condition of a query in another concurrent transaction. For example, once transaction A has executed the query `SELECT ... WHERE class = 1`, a predicate-locking system would forbid transaction B from inserting any new row with class 1 until A has committed. Such a locking system is complex to implement and extremely expensive in execution, since every session must be aware of the details of every query executed by every concurrent transaction. And this large expense is mostly wasted, since in practice most applications do not do the sorts of things that could result in problems. (Certainly the example above is rather contrived and unlikely to represent real software.) For these reasons, PostgreSQL does not implement predicate locking.

In those cases where the possibility of nonserializable execution is a real hazard, problems can be prevented by appropriate use of explicit locking. Further discussion appears in the following sections.

---

1. Essentially, a predicate-locking system prevents phantom reads by restricting what is written, whereas MVCC prevents them by restricting what is read.
Chapter 13. Concurrency Control

13.3. Explicit Locking

PostgreSQL provides various lock modes to control concurrent access to data in tables. These modes can be used for application-controlled locking in situations where MVCC does not give the desired behavior. Also, most PostgreSQL commands automatically acquire locks of appropriate modes to ensure that referenced tables are not dropped or modified in incompatible ways while the command executes. (For example, ALTER TABLE cannot safely be executed concurrently with other operations on the same table, so it obtains an exclusive lock on the table to enforce that.)

To examine a list of the currently outstanding locks in a database server, use the pg_locks system view. For more information on monitoring the status of the lock manager subsystem, refer to Chapter 26.

13.3.1. Table-Level Locks

The list below shows the available lock modes and the contexts in which they are used automatically by PostgreSQL. You can also acquire any of these locks explicitly with the command LOCK. Remember that all of these lock modes are table-level locks, even if the name contains the word “row”; the names of the lock modes are historical. To some extent the names reflect the typical usage of each lock mode — but the semantics are all the same. The only real difference between one lock mode and another is the set of lock modes with which each conflicts (see Table 13-2). Two transactions cannot hold locks of conflicting modes on the same table at the same time. (However, a transaction never conflicts with itself. For example, it might acquire ACCESS EXCLUSIVE lock and later acquire ACCESS SHARE lock on the same table.) Non-conflicting lock modes can be held concurrently by many transactions. Notice in particular that some lock modes are self-conflicting (for example, an ACCESS EXCLUSIVE lock cannot be held by more than one transaction at a time) while others are not self-conflicting (for example, an ACCESS SHARE lock can be held by multiple transactions).

Table-level lock modes

ACCESS SHARE

Conflicts with the ACCESS EXCLUSIVE lock mode only.

The SELECT command acquires a lock of this mode on referenced tables. In general, any query that only reads a table and does not modify it will acquire this lock mode.

ROW SHARE

Conflicts with the EXCLUSIVE and ACCESS EXCLUSIVE lock modes.

The SELECT FOR UPDATE and SELECT FOR SHARE commands acquire a lock of this mode on the target table(s) (in addition to ACCESS SHARE locks on any other tables that are referenced but not selected FOR UPDATE/FOR SHARE).

ROW EXCLUSIVE

Conflicts with the SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, and ACCESS EXCLUSIVE lock modes.

The commands UPDATE, DELETE, and INSERT acquire this lock mode on the target table (in addition to ACCESS SHARE locks on any other referenced tables). In general, this lock mode will be acquired by any command that modifies the data in a table.

SHARE UPDATE EXCLUSIVE

Conflicts with the SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, and ACCESS EXCLUSIVE lock modes. This mode protects a table against
concurrent schema changes and VACUUM runs.

Acquired by VACUUM (without FULL), ANALYZE, and CREATE INDEX CONCURRENTLY.

SHARE

Conflicts with the ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE ROW EXCLUSIVE, EXCLUSIVE, and ACCESS EXCLUSIVE lock modes. This mode protects a table against concurrent data changes.

Acquired by CREATE INDEX (without CONCURRENTLY).

SHARE ROW EXCLUSIVE

Conflicts with the ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, and ACCESS EXCLUSIVE lock modes.

This lock mode is not automatically acquired by any PostgreSQL command.

EXCLUSIVE

Conflicts with the ROW SHARE, ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, and ACCESS EXCLUSIVE lock modes. This mode allows only concurrent ACCESS SHARE locks, i.e., only reads from the table can proceed in parallel with a transaction holding this lock mode.

This lock mode is not automatically acquired on user tables by any PostgreSQL command. However it is acquired on certain system catalogs in some operations.

ACCESS EXCLUSIVE

Conflicts with locks of all modes (ACCESS SHARE, ROW SHARE, ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, and ACCESS EXCLUSIVE). This mode guarantees that the holder is the only transaction accessing the table in any way.

Acquired by the ALTER TABLE, DROP TABLE, TRUNCATE, REINDEX, CLUSTER, and VACUUM FULL commands. This is also the default lock mode for LOCK TABLE statements that do not specify a mode explicitly.

Tip: Only an ACCESS EXCLUSIVE lock blocks a SELECT (without FOR UPDATE/SHARE) statement.

Once acquired, a lock is normally held till end of transaction. But if a lock is acquired after establishing a savepoint, the lock is released immediately if the savepoint is rolled back to. This is consistent with the principle that ROLLBACK cancels all effects of the commands since the savepoint. The same holds for locks acquired within a PL/pgSQL exception block: an error escape from the block releases locks acquired within it.

Table 13-2. Conflicting lock modes

<table>
<thead>

</tr>
<tr>
<td>ACCESS EXCLUSIVE</td>
<td></td>
</tr>
</tbody>
</table>
### 13.3.2. Row-Level Locks

In addition to table-level locks, there are row-level locks, which can be exclusive or shared locks. An exclusive row-level lock on a specific row is automatically acquired when the row is updated or deleted. The lock is held until the transaction commits or rolls back, in just the same way as for table-level locks. Row-level locks do not affect data querying; they block *writers to the same row only.*

To acquire an exclusive row-level lock on a row without actually modifying the row, select the row with `SELECT FOR UPDATE`. Note that once the row-level lock is acquired, the transaction can update the row multiple times without fear of conflicts.

To acquire a shared row-level lock on a row, select the row with `SELECT FOR SHARE`. A shared lock does not prevent other transactions from acquiring the same shared lock. However, no transaction is allowed to update, delete, or exclusively lock a row on which any other transaction holds a shared lock. Any attempt to do so will block until the shared lock(s) have been released.
Chapter 13. Concurrency Control

PostgreSQL doesn’t remember any information about modified rows in memory, so it has no limit to the number of rows locked at one time. However, locking a row might cause a disk write; thus, for example, SELECT FOR UPDATE will modify selected rows to mark them locked, and so will result in disk writes.

In addition to table and row locks, page-level share/exclusive locks are used to control read/write access to table pages in the shared buffer pool. These locks are released immediately after a row is fetched or updated. Application developers normally need not be concerned with page-level locks, but we mention them for completeness.

13.3.3. Deadlocks

The use of explicit locking can increase the likelihood of deadlocks, wherein two (or more) transactions each hold locks that the other wants. For example, if transaction 1 acquires an exclusive lock on table A and then tries to acquire an exclusive lock on table B, while transaction 2 has already exclusive-locked table B and now wants an exclusive lock on table A, then neither one can proceed. PostgreSQL automatically detects deadlock situations and resolves them by aborting one of the transactions involved, allowing the other(s) to complete. (Exactly which transaction will be aborted is difficult to predict and should not be relied on.)

Note that deadlocks can also occur as the result of row-level locks (and thus, they can occur even if explicit locking is not used). Consider the case in which there are two concurrent transactions modifying a table. The first transaction executes:

```
UPDATE accounts SET balance = balance + 100.00 WHERE acctnum = 11111;
```

This acquires a row-level lock on the row with the specified account number. Then, the second transaction executes:

```
UPDATE accounts SET balance = balance + 100.00 WHERE acctnum = 22222;
UPDATE accounts SET balance = balance - 100.00 WHERE acctnum = 11111;
```

The first UPDATE statement successfully acquires a row-level lock on the specified row, so it succeeds in updating that row. However, the second UPDATE statement finds that the row it is attempting to update has already been locked, so it waits for the transaction that acquired the lock to complete. Transaction two is now waiting on transaction one to complete before it continues execution. Now, transaction one executes:

```
UPDATE accounts SET balance = balance - 100.00 WHERE acctnum = 22222;
```

Transaction one attempts to acquire a row-level lock on the specified row, but it cannot: transaction two already holds such a lock. So it waits for transaction two to complete. Thus, transaction one is blocked on transaction two, and transaction two is blocked on transaction one: a deadlock condition. PostgreSQL will detect this situation and abort one of the transactions.

The best defense against deadlocks is generally to avoid them by being certain that all applications using a database acquire locks on multiple objects in a consistent order. In the example above, if both transactions had updated the rows in the same order, no deadlock would have occurred. One should also ensure that the first lock acquired on an object in a transaction is the highest mode that will be needed for that object. If it is not feasible to verify this in advance, then deadlocks can be handled on-the-fly by retrying transactions that are aborted due to deadlock.

So long as no deadlock situation is detected, a transaction seeking either a table-level or row-level lock will wait indefinitely for conflicting locks to be released. This means it is a bad idea for applications to hold transactions open for long periods of time (e.g., while waiting for user input).
Chapter 13. Concurrency Control

13.3.4. Advisory Locks

PostgreSQL provides a means for creating locks that have application-defined meanings. These are called advisory locks, because the system does not enforce their use — it is up to the application to use them correctly. Advisory locks can be useful for locking strategies that are an awkward fit for the MVCC model. Once acquired, an advisory lock is held until explicitly released or the session ends. Unlike standard locks, advisory locks do not honor transaction semantics: a lock acquired during a transaction that is later rolled back will still be held following the rollback, and likewise an unlock is effective even if the calling transaction fails later. The same lock can be acquired multiple times by its owning process; for each lock request there must be a corresponding unlock request before the lock is actually released. (If a session already holds a given lock, additional requests will always succeed, even if other sessions are awaiting the lock.) Like all locks in PostgreSQL, a complete list of advisory locks currently held by any session can be found in the pg_locks system view.

Advisory locks are allocated out of a shared memory pool whose size is defined by the configuration variables max_locks_per_transaction and max_connections. Care must be taken not to exhaust this memory or the server will not be able to grant any locks at all. This imposes an upper limit on the number of advisory locks grantable by the server, typically in the tens to hundreds of thousands depending on how the server is configured.

A common use of advisory locks is to emulate pessimistic locking strategies typical of so called “flat file” data management systems. While a flag stored in a table could be used for the same purpose, advisory locks are faster, avoid MVCC bloat, and are automatically cleaned up by the server at the end of the session. In certain cases using this method, especially in queries involving explicit ordering and LIMIT clauses, care must be taken to control the locks acquired because of the order in which SQL expressions are evaluated. For example:

```sql
SELECT pg_advisory_lock(id) FROM foo WHERE id = 12345; -- ok
SELECT pg_advisory_lock(id) FROM foo WHERE id > 12345 LIMIT 100; -- danger!
SELECT pg_advisory_lock(q.id) FROM
  (SELECT id FROM foo WHERE id > 12345 LIMIT 100;
   q;
  ) q; -- ok
```

In the above queries, the second form is dangerous because the LIMIT is not guaranteed to be applied before the locking function is executed. This might cause some locks to be acquired that the application was not expecting, and hence would fail to release (until it ends the session). From the point of view of the application, such locks would be dangling, although still viewable in pg_locks.

The functions provided to manipulate advisory locks are described in Table 9-56.

13.4. Data Consistency Checks at the Application Level

Because readers in PostgreSQL do not lock data, regardless of transaction isolation level, data read by one transaction can be overwritten by another concurrent transaction. In other words, if a row is returned by SELECT it doesn’t mean that the row is still current at the instant it is returned (i.e., sometime after the current query began). The row might have been modified or deleted by an already-committed transaction that committed after this one started. Even if the row is still valid “now”, it could be changed or deleted before the current transaction does a commit or rollback.

Another way to think about it is that each transaction sees a snapshot of the database contents, and concurrently executing transactions might very well see different snapshots. So the whole concept of “now” is somewhat ill-defined anyway. This is not normally a big problem if the client applications...
are isolated from each other, but if the clients can communicate via channels outside the database then serious confusion might ensue.

To ensure the current validity of a row and protect it against concurrent updates one must use `SELECT FOR UPDATE`, `SELECT FOR SHARE`, or an appropriate `LOCK TABLE` statement. (`SELECT FOR UPDATE` or `SELECT FOR SHARE` locks just the returned rows against concurrent updates, while `LOCK TABLE` locks the whole table.) This should be taken into account when porting applications to PostgreSQL from other environments.

Global validity checks require extra thought under MVCC. For example, a banking application might wish to check that the sum of all credits in one table equals the sum of debits in another table, when both tables are being actively updated. Comparing the results of two successive `SELECT sum(...)` commands will not work reliably under Read Committed mode, since the second query will likely include the results of transactions not counted by the first. Doing the two sums in a single serializable transaction will give an accurate picture of the effects of transactions that committed before the serializable transaction started — but one might legitimately wonder whether the answer is still relevant by the time it is delivered. If the serializable transaction itself applied some changes before trying to make the consistency check, the usefulness of the check becomes even more debatable, since now it includes some but not all post-transaction-start changes. In such cases a careful person might wish to lock all tables needed for the check, in order to get an indisputable picture of current reality. A `SHARE` mode (or higher) lock guarantees that there are no uncommitted changes in the locked table, other than those of the current transaction.

Note also that if one is relying on explicit locking to prevent concurrent changes, one should use Read Committed mode, or in Serializable mode be careful to obtain the lock(s) before performing queries. A lock obtained by a serializable transaction guarantees that no other transactions modifying the table are still running, but if the snapshot seen by the transaction predates obtaining the lock, it might predate some now-committed changes in the table. A serializable transaction’s snapshot is actually frozen at the start of its first query or data-modification command (`SELECT`, `INSERT`, `UPDATE`, or `DELETE`), so it’s possible to obtain locks explicitly before the snapshot is frozen.

### 13.5. Locking and Indexes

Though PostgreSQL provides nonblocking read/write access to table data, nonblocking read/write access is not currently offered for every index access method implemented in PostgreSQL. The various index types are handled as follows:

**B-tree and GiST indexes**

Short-term share/exclusive page-level locks are used for read/write access. Locks are released immediately after each index row is fetched or inserted. These index types provide the highest concurrency without deadlock conditions.

**Hash indexes**

Share/exclusive hash-bucket-level locks are used for read/write access. Locks are released after the whole bucket is processed. Bucket-level locks provide better concurrency than index-level ones, but deadlock is possible since the locks are held longer than one index operation.

**GIN indexes**

Short-term share/exclusive page-level locks are used for read/write access. Locks are released immediately after each index row is fetched or inserted. But note that a GIN-indexed value insertion usually produces several index key insertions per row, so GIN might do substantial work for a single value’s insertion.
Currently, B-tree indexes offer the best performance for concurrent applications; since they also have more features than hash indexes, they are the recommended index type for concurrent applications that need to index scalar data. When dealing with non-scalar data, B-trees are not useful, and GiST or GIN indexes should be used instead.
Chapter 14. Performance Tips

Query performance can be affected by many things. Some of these can be manipulated by the user, while others are fundamental to the underlying design of the system. This chapter provides some hints about understanding and tuning PostgreSQL performance.

14.1. Using EXPLAIN

PostgreSQL devises a query plan for each query it is given. Choosing the right plan to match the query structure and the properties of the data is absolutely critical for good performance, so the system includes a complex planner that tries to select good plans. You can use the EXPLAIN command to see what query plan the planner creates for any query. Plan-reading is an art that deserves an extensive tutorial, which this is not; but here is some basic information.

The structure of a query plan is a tree of plan nodes. Nodes at the bottom level are table scan nodes: they return raw rows from a table. There are different types of scan nodes for different table access methods: sequential scans, index scans, and bitmap index scans. If the query requires joining, aggregation, sorting, or other operations on the raw rows, then there will be additional nodes “atop” the scan nodes to perform these operations. Again, there is usually more than one possible way to do these operations, so different node types can appear here too. The output of EXPLAIN has one line for each node in the plan tree, showing the basic node type plus the cost estimates that the planner made for the execution of that plan node. The first line (topmost node) has the estimated total execution cost for the plan; it is this number that the planner seeks to minimize.

Here is a trivial example, just to show what the output looks like.¹

EXPLAIN SELECT * FROM tenk1;

QUERY PLAN

-------------------------------------------------------------
Seq Scan on tenk1 (cost=0.00..458.00 rows=10000 width=244)

The numbers that are quoted by EXPLAIN are:

- Estimated start-up cost (Time expended before output scan can start, e.g., time to do the sorting in a sort node.)
- Estimated total cost (If all rows were to be retrieved, though they might not be: for example, a query with a LIMIT clause will stop short of paying the total cost of the Limit plan node’s input node.)
- Estimated number of rows output by this plan node (Again, only if executed to completion.)
- Estimated average width (in bytes) of rows output by this plan node

The costs are measured in arbitrary units determined by the planner’s cost parameters (see Section 18.6.2). Traditional practice is to measure the costs in units of disk page fetches; that is, seq_page_cost is conventionally set to 1.0 and the other cost parameters are set relative to that. The examples in this section are run with the default cost parameters.

¹ Examples in this section are drawn from the regression test database after doing a VACUUM ANALYZE, using 8.2 development sources. You should be able to get similar results if you try the examples yourself, but your estimated costs and row counts will probably vary slightly because ANALYZE’s statistics are random samples rather than being exact.
It’s important to note that the cost of an upper-level node includes the cost of all its child nodes. It’s also important to realize that the cost only reflects things that the planner cares about. In particular, the cost does not consider the time spent transmitting result rows to the client, which could be an important factor in the true elapsed time; but the planner ignores it because it cannot change it by altering the plan. (Every correct plan will output the same row set, we trust.)

Rows output is a little tricky because it is not the number of rows processed or scanned by the plan node. It is usually less, reflecting the estimated selectivity of any WHERE-clause conditions that are being applied at the node. Ideally the top-level rows estimate will approximate the number of rows actually returned, updated, or deleted by the query.

Returning to our example:

```
EXPLAIN SELECT * FROM tenk1;
```

```
QUERY PLAN

Seq Scan on tenk1 (cost=0.00..458.00 rows=10000 width=244)
```

This is about as straightforward as it gets. If you do:

```
SELECT relpages, reltuples FROM pg_class WHERE relname = 'tenk1';
```

you will find out that tenk1 has 358 disk pages and 10000 rows. The estimated cost is (disk pages read * seq_page_cost) + (rows scanned * cpu_tuple_cost). By default, seq_page_cost is 1.0 and cpu_tuple_cost is 0.01. So the estimated cost is (358 * 1.0) + (10000 * 0.01) = 458.

Now let’s modify the query to add a WHERE condition:

```
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 7000;
```

```
QUERY PLAN

Seq Scan on tenk1 (cost=0.00..483.00 rows=7033 width=244)
  Filter: (unique1 < 7000)
```

Notice that the EXPLAIN output shows the WHERE clause being applied as a “filter” condition; this means that the plan node checks the condition for each row it scans, and outputs only the ones that pass the condition. The estimate of output rows has gone down because of the WHERE clause. However, the scan will still have to visit all 10000 rows, so the cost hasn’t decreased; in fact it has gone up a bit (by 10000 * cpu_operator_cost, to be exact) to reflect the extra CPU time spent checking the WHERE condition.

The actual number of rows this query would select is 7000, but the rows estimate is only approximate. If you try to duplicate this experiment, you will probably get a slightly different estimate; moreover, it will change after each ANALYZE command, because the statistics produced by ANALYZE are taken from a randomized sample of the table.

Now, let’s make the condition more restrictive:

```
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 100;
```

```
QUERY PLAN

Bitmap Heap Scan on tenk1 (cost=2.37..232.35 rows=106 width=244)
  Recheck Cond: (unique1 < 100)
  -> Bitmap Index Scan on tenk1_unique1 (cost=0.00..2.37 rows=106 width=0)
```
Chapter 14. Performance Tips

Here the planner has decided to use a two-step plan: the bottom plan node visits an index to find the locations of rows matching the index condition, and then the upper plan node actually fetches those rows from the table itself. Fetching the rows separately is much more expensive than sequentially reading them, but because not all the pages of the table have to be visited, this is still cheaper than a sequential scan. (The reason for using two levels of plan is that the upper plan node sorts the row locations identified by the index into physical order before reading them, so as to minimize the costs of the separate fetches. The “bitmap” mentioned in the node names is the mechanism that does the sorting.)

If the WHERE condition is selective enough, the planner might switch to a “simple” index scan plan:

```sql
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 3;
```

```sql
QUERY PLAN
------------------------------------------------------------------------------
Index Scan using tenk1_unique1 on tenk1 (cost=0.00..10.00 rows=2 width=244)
  Index Cond: (unique1 < 3)
In this case the table rows are fetched in index order, which makes them even more expensive to read, but there are so few that the extra cost of sorting the row locations is not worth it. You’ll most often see this plan type for queries that fetch just a single row, and for queries that request an ORDER BY condition that matches the index order.

Add another condition to the WHERE clause:

```sql
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 3 AND stringu1 = 'xxx';
```

```sql
QUERY PLAN
------------------------------------------------------------------------------
Index Scan using tenk1_unique1 on tenk1 (cost=0.00..10.01 rows=1 width=244)
  Index Cond: (unique1 < 3)
  Filter: (stringu1 = 'xxx'::name)
The added condition stringu1 = 'xxx' reduces the output-rows estimate, but not the cost because we still have to visit the same set of rows. Notice that the stringu1 clause cannot be applied as an index condition (since this index is only on the unique1 column). Instead it is applied as a filter on the rows retrieved by the index. Thus the cost has actually gone up a little bit to reflect this extra checking.

If there are indexes on several columns used in WHERE, the planner might choose to use an AND or OR combination of the indexes:

```sql
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 100 AND unique2 > 9000;
```

```sql
QUERY PLAN
------------------------------------------------------------------------------
Bitmap Heap Scan on tenk1 (cost=11.27..49.11 rows=11 width=244)
  Recheck Cond: ((unique1 < 100) AND (unique2 > 9000))
  -> BitmapAnd (cost=11.27..11.27 rows=11 width=0)
    -> Bitmap Index Scan on tenk1_unique1 (cost=0.00..2.37 rows=106 width=0)
      Index Cond: (unique1 < 100)
    -> Bitmap Index Scan on tenk1_unique2 (cost=0.00..8.65 rows=1042 width=0)
      Index Cond: (unique2 > 9000)
Chapter 14. Performance Tips

But this requires visiting both indexes, so it’s not necessarily a win compared to using just one index and treating the other condition as a filter. If you vary the ranges involved you’ll see the plan change accordingly.

Let’s try joining two tables, using the columns we have been discussing:

```
EXPLAIN SELECT * FROM tenk1 t1, tenk2 t2 WHERE t1.unique1 < 100 AND t1.unique2 = t2.unique2;
```

**QUERY PLAN**

```
--------------------------------------------------------------------------------------
| Nested Loop (cost=2.37..553.11 rows=106 width=488) |
| -> Bitmap Heap Scan on tenk1 t1 (cost=2.37..232.35 rows=106 width=244) |
| | Recheck Cond: (unique1 < 100) |
| | -> Bitmap Index Scan on tenk1_unique1 (cost=0.00..2.37 rows=106 width=0) |
| | | Index Cond: (unique1 < 100) |
| | -> Index Scan using tenk2_unique2 on tenk2 t2 (cost=0.00..3.01 rows=1 width=244) |
| | | Index Cond: (t2.unique2 = t1.unique2) |
--------------------------------------------------------------------------------------
```

In this nested-loop join, the outer scan is the same bitmap index scan we saw earlier, and so its cost and row count are the same because we are applying the `WHERE` clause `unique1 < 100` at that node. The `t1.unique2 = t2.unique2` clause is not relevant yet, so it doesn’t affect row count of the outer scan. For the inner scan, the `unique2` value of the current outer-scan row is plugged into the inner index scan to produce an index condition like `t2.unique2 = constant`. So we get the same inner-scan plan and costs that we’d get from, say, `EXPLAIN SELECT * FROM tenk2 WHERE unique2 = 42`. The costs of the loop node are then set on the basis of the cost of the outer scan, plus one repetition of the inner scan for each outer row (106 * 3.01, here), plus a little CPU time for join processing.

In this example the join’s output row count is the same as the product of the two scans’ row counts, but that’s not true in general, because in general you can have `WHERE` clauses that mention both tables and so can only be applied at the join point, not to either input scan. For example, if we added `WHERE ... AND t1.hundred < t2.hundred`, that would decrease the output row count of the join node, but not change either input scan.

One way to look at variant plans is to force the planner to disregard whatever strategy it thought was the winner, using the enable/disable flags described in Section 18.6.1. (This is a crude tool, but useful. See also Section 14.3.)

```
SET enable_nestloop = off;
EXPLAIN SELECT * FROM tenk1 t1, tenk2 t2 WHERE t1.unique1 < 100 AND t1.unique2 = t2.unique2;
```

**QUERY PLAN**

```
------------------------------------------------------------------------------------------
| Hash Join (cost=232.61..741.67 rows=106 width=488) |
| Hash Cond: (t2.unique2 = t1.unique2) |
| -> Seq Scan on tenk2 t2 (cost=0.00..458.00 rows=10000 width=244) |
| -> Hash (cost=232.35..232.35 rows=106 width=244) |
| | -> Bitmap Heap Scan on tenk1 t1 (cost=2.37..232.35 rows=106 width=244) |
| | | Recheck Cond: (unique1 < 100) |
| | | -> Bitmap Index Scan on tenk1_unique1 (cost=0.00..2.37 rows=106 width=0) |
| | | | Index Cond: (unique1 < 100) |
------------------------------------------------------------------------------------------
```

This plan proposes to extract the 100 interesting rows of `tenk1` using that same old index scan, stash them into an in-memory hash table, and then do a sequential scan of `tenk2`, probing into the hash table for possible matches of `t1.unique2 = t2.unique2` at each `tenk2` row. The cost to read...
tenk1 and set up the hash table is entirely start-up cost for the hash join, since we won’t get any rows out until we can start reading tenk2. The total time estimate for the join also includes a hefty charge for the CPU time to probe the hash table 10000 times. Note, however, that we are not charging 10000 times 232.35; the hash table setup is only done once in this plan type.

It is possible to check on the accuracy of the planner’s estimated costs by using EXPLAIN ANALYZE. This command actually executes the query, and then displays the true run time accumulated within each plan node along with the same estimated costs that a plain EXPLAIN shows. For example, we might get a result like this:

```sql
EXPLAIN ANALYZE SELECT * FROM tenk1 t1, tenk2 t2 WHERE t1.unique1 < 100 AND t1.unique2 = t2.unique2;
```

```
QUERY PLAN
----------------------------------------------------------------------------------------------------------------------------------
Nested Loop  (cost=2.37..553.11 rows=106 width=488) (actual time=1.392..12.700 rows=100 loops=1)
  ->  Bitmap Heap Scan on tenk1 t1  (cost=2.37..232.35 rows=106 width=244) (actual time=0.878..2.367 rows=100 loops=1)
      Recheck Cond: (unique1 < 100)
  ->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..2.37 rows=106 width=0) (actual time=0.546..0.546 rows=100 loops=1)
      Index Cond: (unique1 < 100)
  ->  Index Scan using tenk2_unique2 on tenk2 t2  (cost=0.00..3.01 rows=1 width=244) (actual time=0.067..0.078 rows=1 loops=100)
      Index Cond: (t2.unique2 = t1.unique2)
Total runtime: 14.452 ms
```

Note that the “actual time” values are in milliseconds of real time, whereas the “cost” estimates are expressed in arbitrary units; so they are unlikely to match up. The thing to pay attention to is whether the ratios of actual time and estimated costs are consistent.

In some query plans, it is possible for a subplan node to be executed more than once. For example, the inner index scan is executed once per outer row in the above nested-loop plan. In such cases, the “loops” value reports the total number of executions of the node, and the actual time and rows values shown are averages per-execution. This is done to make the numbers comparable with the way that the cost estimates are shown. Multiply by the “loops” value to get the total time actually spent in the node.

The Total runtime shown by EXPLAIN ANALYZE includes executor start-up and shut-down time, as well as time spent processing the result rows. It does not include parsing, rewriting, or planning time. For a SELECT query, the total run time will normally be just a little larger than the total time reported for the top-level plan node. For INSERT, UPDATE, and DELETE commands, the total run time might be considerably larger, because it includes the time spent processing the result rows. In these commands, the time for the top plan node essentially is the time spent computing the new rows and/or locating the old ones, but it doesn’t include the time spent applying the changes. Time spent firing triggers, if any, is also outside the top plan node, and is shown separately for each trigger.

It is worth noting that EXPLAIN results should not be extrapolated to situations other than the one you are actually testing; for example, results on a toy-sized table cannot be assumed to apply to large tables. The planner’s cost estimates are not linear and so it might choose a different plan for a larger or smaller table. An extreme example is that on a table that only occupies one disk page, you’ll nearly always get a sequential scan plan whether indexes are available or not. The planner realizes that it’s going to take one disk page read to process the table in any case, so there’s no value in expending additional page reads to look at an index.
14.2. Statistics Used by the Planner

As we saw in the previous section, the query planner needs to estimate the number of rows retrieved by a query in order to make good choices of query plans. This section provides a quick look at the statistics that the system uses for these estimates.

One component of the statistics is the total number of entries in each table and index, as well as the number of disk blocks occupied by each table and index. This information is kept in the table `pg_class`, in the columns `reltuples` and `relpages`. We can look at it with queries similar to this one:

```
SELECT relname, relkind, reltuples, relpages FROM pg_class WHERE relname LIKE 'tenk1%';
```

<table>
<thead>
<tr>
<th>relname</th>
<th>relkind</th>
<th>reltuples</th>
<th>relpages</th>
</tr>
</thead>
<tbody>
<tr>
<td>tenk1</td>
<td>r</td>
<td>10000</td>
<td>358</td>
</tr>
<tr>
<td>tenk1_hundred</td>
<td>i</td>
<td>10000</td>
<td>30</td>
</tr>
<tr>
<td>tenk1_thous_tenthous</td>
<td>i</td>
<td>10000</td>
<td>30</td>
</tr>
<tr>
<td>tenk1_unique1</td>
<td>i</td>
<td>10000</td>
<td>30</td>
</tr>
<tr>
<td>tenk1_unique2</td>
<td>i</td>
<td>10000</td>
<td>30</td>
</tr>
</tbody>
</table>

Here we can see that `tenk1` contains 10000 rows, as do its indexes, but the indexes are (unsurprisingly) much smaller than the table.

For efficiency reasons, `reltuples` and `relpages` are not updated on-the-fly, and so they usually contain somewhat out-of-date values. They are updated by `VACUUM`, `ANALYZE`, and a few DDL commands such as `CREATE INDEX`. A stand-alone `ANALYZE`, that is one not part of `VACUUM`, generates an approximate `reltuples` value since it does not read every row of the table. The planner will scale the values it finds in `pg_class` to match the current physical table size, thus obtaining a closer approximation.

Most queries retrieve only a fraction of the rows in a table, due to having `WHERE` clauses that restrict the rows to be examined. The planner thus needs to make an estimate of the selectivity of `WHERE` clauses, that is, the fraction of rows that match each condition in the `WHERE` clause. The information used for this task is stored in the `pg_statistic` system catalog. Entries in `pg_statistic` are updated by the `ANALYZE` and `VACUUM ANALYZE` commands, and are always approximate even when freshly updated.

Rather than look at `pg_statistic` directly, it’s better to look at its view `pg_stats` when examining the statistics manually. `pg_stats` is designed to be more easily readable. Furthermore, `pg_stats` is readable by all, whereas `pg_statistic` is only readable by a superuser. (This prevents unprivileged users from learning something about the contents of other people’s tables from the statistics. The `pg_stats` view is restricted to show only rows about tables that the current user can read.) For example, we might do:

```
SELECT attname, n_distinct, most_common_vals FROM pg_stats WHERE tablename = 'road';
```

<table>
<thead>
<tr>
<th>attname</th>
<th>n_distinct</th>
<th>most_common_vals</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>-0.467008</td>
<td>(&quot;I- 580 Ramp&quot;,&quot;I- 880 Ramp&quot;,&quot;I- 580&quot;,&quot;I- 680 Ramp&quot;,&quot;I- 80 Ramp&quot;,&quot;14th St&quot;,&quot;5th St&quot;,&quot;Mission Blvd&quot;,&quot;I- 880&quot;)</td>
</tr>
<tr>
<td>thepath</td>
<td>20</td>
<td>(&quot;([-122.089,37.71),(-122.088,37.711)]&quot;)</td>
</tr>
</tbody>
</table>

(2 rows)
The amount of information stored in `pg_statistic` by `ANALYZE`, in particular the maximum number of entries in the `most_common_vals` and `histogram_bounds` arrays for each column, can be set on a column-by-column basis using the `ALTER TABLE SET STATISTICS` command, or globally by setting the `default_statistics_target` configuration variable. The default limit is presently 10 entries. Raising the limit might allow more accurate planner estimates to be made, particularly for columns with irregular data distributions, at the price of consuming more space in `pg_statistic` and slightly more time to compute the estimates. Conversely, a lower limit might be sufficient for columns with simple data distributions.

Further details about the planner’s use of statistics can be found in Chapter 55.

### 14.3. Controlling the Planner with Explicit `JOIN` Clauses

It is possible to control the query planner to some extent by using the explicit `JOIN` syntax. To see why this matters, we first need some background.

In a simple join query, such as:

```sql
SELECT * FROM a, b, c WHERE a.id = b.id AND b.ref = c.id;
```

the planner is free to join the given tables in any order. For example, it could generate a query plan that joins A to B, using the `WHERE` condition `a.id = b.id`, and then joins C to this joined table, using the other `WHERE` condition. Or it could join B to C and then join A to that result. Or it could join A to C and then join them with B — but that would be inefficient, since the full Cartesian product of A and C would have to be formed, there being no applicable condition in the `WHERE` clause to allow optimization of the join. (All joins in the PostgreSQL executor happen between two input tables, so it’s necessary to build up the result in one or another of these fashions.) The important point is that these different join possibilities give semantically equivalent results but might have hugely different execution costs. Therefore, the planner will explore all of them to try to find the most efficient query plan.

When a query only involves two or three tables, there aren’t many join orders to worry about. But the number of possible join orders grows exponentially as the number of tables expands. Beyond ten or so input tables it’s no longer practical to do an exhaustive search of all the possibilities, and even for six or seven tables planning might take an annoyingly long time. When there are too many input tables, the PostgreSQL planner will switch from exhaustive search to a genetic probabilistic search through a limited number of possibilities. (The switch-over threshold is set by the `geqo_threshold` run-time parameter.) The genetic search takes less time, but it won’t necessarily find the best possible plan.

When the query involves outer joins, the planner has less freedom than it does for plain (inner) joins. For example, consider:

```sql
SELECT * FROM a LEFT JOIN (b JOIN c ON (b.ref = c.id)) ON (a.id = b.id);
```

Although this query’s restrictions are superficially similar to the previous example, the semantics are different because a row must be emitted for each row of A that has no matching row in the join of B and C. Therefore the planner has no choice of join order here: it must join B to C and then join A to that result. Accordingly, this query takes less time to plan than the previous query. In other cases, the planner might be able to determine that more than one join order is safe. For example, given:

```sql
SELECT * FROM a LEFT JOIN b ON (a.bid = b.id) LEFT JOIN c ON (a.cid = c.id);
```

it is valid to join A to either B or C first. Currently, only `FULL JOIN` completely constrains the join order. Most practical cases involving `LEFT JOIN` or `RIGHT JOIN` can be rearranged to some extent.
Explicit inner join syntax (INNER JOIN, CROSS JOIN, or unadorned JOIN) is semantically the same as listing the input relations in FROM, so it does not constrain the join order.

Even though most kinds of JOIN don’t completely constrain the join order, it is possible to instruct the PostgreSQL query planner to treat all JOIN clauses as constraining the join order anyway. For example, these three queries are logically equivalent:

```sql
SELECT * FROM a, b, c WHERE a.id = b.id AND b.ref = c.id;
SELECT * FROM a CROSS JOIN b CROSS JOIN c WHERE a.id = b.id AND b.ref = c.id;
SELECT * FROM a JOIN (b JOIN c ON (b.ref = c.id)) ON (a.id = b.id);
```

But if we tell the planner to honor the JOIN order, the second and third take less time to plan than the first. This effect is not worth worrying about for only three tables, but it can be a lifesaver with many tables.

To force the planner to follow the join order laid out by explicit JOINs, set the join_collapse_limit run-time parameter to 1. (Other possible values are discussed below.)

You do not need to constrain the join order completely in order to cut search time, because it’s OK to use JOIN operators within items of a plain FROM list. For example, consider:

```sql
SELECT * FROM a CROSS JOIN b, c, d, e WHERE ...
```

With join_collapse_limit = 1, this forces the planner to join A to B before joining them to other tables, but doesn’t constrain its choices otherwise. In this example, the number of possible join orders is reduced by a factor of 5.

Constraining the planner’s search in this way is a useful technique both for reducing planning time and for directing the planner to a good query plan. If the planner chooses a bad join order by default, you can force it to choose a better order via JOIN syntax — assuming that you know of a better order, that is. Experimentation is recommended.

A closely related issue that affects planning time is collapsing of subqueries into their parent query. For example, consider:

```sql
SELECT *
FROM x, y,
    (SELECT * FROM a, b, c WHERE something) AS ss
WHERE somethingelse;
```

This situation might arise from use of a view that contains a join; the view’s SELECT rule will be inserted in place of the view reference, yielding a query much like the above. Normally, the planner will try to collapse the subquery into the parent, yielding:

```sql
SELECT * FROM x, y, a, b, c WHERE something AND somethingelse;
```

This usually results in a better plan than planning the subquery separately. (For example, the outer WHERE conditions might be such that joining X to A first eliminates many rows of A, thus avoiding the need to form the full logical output of the subquery.) But at the same time, we have increased the planning time; here, we have a five-way join problem replacing two separate three-way join problems. Because of the exponential growth of the number of possibilities, this makes a big difference. The planner tries to avoid getting stuck in huge join search problems by not collapsing a subquery if more than fromCollapse_limit FROM items would result in the parent query. You can trade off planning time against quality of plan by adjusting this run-time parameter up or down.

fromCollapse_limit and join_collapse_limit are similarly named because they do almost the same thing: one controls when the planner will “flatten out” subqueries, and the other controls when it will flatten out explicit joins. Typically you would either set join_collapse_limit
equal to `fromCollapseLimit` (so that explicit joins and subqueries act similarly) or set `join CollapseLimit` to 1 (if you want to control join order with explicit joins). But you might set them differently if you are trying to fine-tune the trade-off between planning time and run time.

### 14.4. Populating a Database

One might need to insert a large amount of data when first populating a database. This section contains some suggestions on how to make this process as efficient as possible.

#### 14.4.1. Disable Autocommit

Turn off autocommit and just do one commit at the end. (In plain SQL, this means issuing `BEGIN` at the start and `COMMIT` at the end. Some client libraries might do this behind your back, in which case you need to make sure the library does it when you want it done.) If you allow each insertion to be committed separately, PostgreSQL is doing a lot of work for each row that is added. An additional benefit of doing all insertions in one transaction is that if the insertion of one row were to fail then the insertion of all rows inserted up to that point would be rolled back, so you won’t be stuck with partially loaded data.

#### 14.4.2. Use `COPY`

Use `COPY` to load all the rows in one command, instead of using a series of `INSERT` commands. The `COPY` command is optimized for loading large numbers of rows; it is less flexible than `INSERT`, but incurs significantly less overhead for large data loads. Since `COPY` is a single command, there is no need to disable autocommit if you use this method to populate a table.

If you cannot use `COPY`, it might help to use `PREPARE` to create a prepared `INSERT` statement, and then use `EXECUTE` as many times as required. This avoids some of the overhead of repeatedly parsing and planning `INSERT`. Different interfaces provide this facility in different ways; look for “prepared statements” in the interface documentation.

Note that loading a large number of rows using `COPY` is almost always faster than using `INSERT`, even if `PREPARE` is used and multiple insertions are batched into a single transaction.

`COPY` is fastest when used within the same transaction as an earlier `CREATE TABLE` or `TRUNCATE` command. In such cases no WAL needs to be written, because in case of an error, the files containing the newly loaded data will be removed anyway. However, this consideration does not apply when `archive_mode` is set, as all commands must write WAL in that case.

#### 14.4.3. Remove Indexes

If you are loading a freshly created table, the fastest way is to create the table, bulk load the table’s data using `COPY`, then create any indexes needed for the table. Creating an index on pre-existing data is quicker than updating it incrementally as each row is loaded.

If you are adding large amounts of data to an existing table, it might be a win to drop the index, load the table, and then recreate the index. Of course, the database performance for other users might be adversely affected during the time that the index is missing. One should also think twice before dropping unique indexes, since the error checking afforded by the unique constraint will be lost while the index is missing.
14.4.4. Remove Foreign Key Constraints

Just as with indexes, a foreign key constraint can be checked “in bulk” more efficiently than row-by-row. So it might be useful to drop foreign key constraints, load data, and re-create the constraints. Again, there is a trade-off between data load speed and loss of error checking while the constraint is missing.

14.4.5. Increase maintenance_work_mem

Temporarily increasing the maintenance_work_mem configuration variable when loading large amounts of data can lead to improved performance. This will help to speed up CREATE INDEX commands and ALTER TABLE ADD FOREIGN KEY commands. It won’t do much for COPY itself, so this advice is only useful when you are using one or both of the above techniques.

14.4.6. Increase checkpoint_segments

Temporarily increasing the checkpoint_segments configuration variable can also make large data loads faster. This is because loading a large amount of data into PostgreSQL will cause checkpoints to occur more often than the normal checkpoint frequency (specified by the checkpoint_timeout configuration variable). Whenever a checkpoint occurs, all dirty pages must be flushed to disk. By increasing checkpoint_segments temporarily during bulk data loads, the number of checkpoints that are required can be reduced.

14.4.7. Turn off archive_mode

When loading large amounts of data into an installation that uses WAL archiving, you might want to disable archiving (turn off the archive_mode configuration variable) while loading. It might be faster to take a new base backup after the load has completed than to process a large amount of incremental WAL data. But note that turning archive_mode on or off requires a server restart.

Aside from avoiding the time for the archiver to process the WAL data, doing this will actually make certain commands faster, because they are designed not to write WAL at all if archive_mode is off. (They can guarantee crash safety more cheaply by doing an fsync at the end than by writing WAL.) This applies to the following commands:

• CREATE TABLE AS SELECT
• CREATE INDEX (and variants such as ALTER TABLE ADD PRIMARY KEY)
• ALTER TABLE SET TABLESPACE
• CLUSTER
• COPY FROM, when the target table has been created or truncated earlier in the same transaction

14.4.8. Run ANALYZE Afterwards

Whenever you have significantly altered the distribution of data within a table, running ANALYZE is strongly recommended. This includes bulk loading large amounts of data into the table. Running ANALYZE (or VACUUM ANALYZE) ensures that the planner has up-to-date statistics about the table.
Chapter 14. Performance Tips

With no statistics or obsolete statistics, the planner might make poor decisions during query planning, leading to poor performance on any tables with inaccurate or nonexistent statistics.

14.4.9. Some Notes About pg_dump

Dump scripts generated by pg_dump automatically apply several, but not all, of the above guidelines. To reload a pg_dump dump as quickly as possible, you need to do a few extra things manually. (Note that these points apply while restoring a dump, not while creating it. The same points apply when using pg_restore to load from a pg_dump archive file.)

By default, pg_dump uses COPY, and when it is generating a complete schema-and-data dump, it is careful to load data before creating indexes and foreign keys. So in this case several guidelines are handled automatically. What is left for you to do is to:

- Set appropriate (i.e., larger than normal) values for maintenance_work_mem and checkpoint_segments.
- If using WAL archiving, consider disabling it during the restore. To do that, turn off archive_mode before loading the dump script, and afterwards turn it back on and take a fresh base backup.
- Consider whether the whole dump should be restored as a single transaction. To do that, pass the -1 or --single-transaction command-line option to psql or pg_restore. When using this mode, even the smallest of errors will rollback the entire restore, possibly discarding many hours of processing. Depending on how interrelated the data is, that might seem preferable to manual cleanup, or not. COPY commands will run fastest if you use a single transaction and have WAL archiving turned off.
- Run ANALYZE afterwards.

A data-only dump will still use COPY, but it does not drop or recreate indexes, and it does not normally touch foreign keys. So when loading a data-only dump, it is up to you to drop and recreate indexes and foreign keys if you wish to use those techniques. It’s still useful to increase checkpoint_segments while loading the data, but don’t bother increasing maintenance_work_mem; rather, you’d do that while manually recreating indexes and foreign keys afterwards. And don’t forget to ANALYZE when you’re done.

2. You can get the effect of disabling foreign keys by using the --disable-triggers option — but realize that that eliminates, rather than just postpones, foreign key validation, and so it is possible to insert bad data if you use it.
III. Server Administration

This part covers topics that are of interest to a PostgreSQL database administrator. This includes installation of the software, set up and configuration of the server, management of users and databases, and maintenance tasks. Anyone who runs a PostgreSQL server, even for personal use, but especially in production, should be familiar with the topics covered in this part.

The information in this part is arranged approximately in the order in which a new user should read it. But the chapters are self-contained and can be read individually as desired. The information in this part is presented in a narrative fashion in topical units. Readers looking for a complete description of a particular command should look into Part VI.

The first few chapters are written so that they can be understood without prerequisite knowledge, so that new users who need to set up their own server can begin their exploration with this part. The rest of this part is about tuning and management; that material assumes that the reader is familiar with the general use of the PostgreSQL database system. Readers are encouraged to look at Part I and Part II for additional information.
Chapter 15. Installation Instructions

This chapter describes the installation of PostgreSQL from the source code distribution. (If you are installing a pre-packaged distribution, such as an RPM or Debian package, ignore this chapter and read the packager’s instructions instead.)

15.1. Short Version

./configure
gmake
su
gmake install
adduser postgres
mkdir /usr/local/pgsql/data
chown postgres /usr/local/pgsql/data
su - postgres
/usr/local/pgsql/bin/initdb -D /usr/local/pgsql/data
/usr/local/pgsql/bin/postgres -D /usr/local/pgsql/data >logfile 2>&1 &
/usr/local/pgsql/bin/createdb test
/usr/local/pgsql/bin/psql test

The long version is the rest of this chapter.

15.2. Requirements

In general, a modern Unix-compatible platform should be able to run PostgreSQL. The platforms that had received specific testing at the time of release are listed in Section 15.7 below. In the doc subdirectory of the distribution there are several platform-specific FAQ documents you might wish to consult if you are having trouble.

The following software packages are required for building PostgreSQL:

- GNU make is required; other make programs will not work. GNU make is often installed under the name gmake; this document will always refer to it by that name. (On some systems GNU make is the default tool with the name make.) To test for GNU make enter

  gmake --version

  It is recommended to use version 3.76.1 or later.

- You need an ISO/ANSI C compiler. Recent versions of GCC are recommendable, but PostgreSQL is known to build with a wide variety of compilers from different vendors.

- tar is required to unpack the source distribution in the first place, in addition to either gzip or bzip2.

- The GNU Readline library (for simple line editing and command history retrieval) is used by default. If you don’t want to use it then you must specify the --without-readline option for configure. As an alternative, you can often use the BSD-licensed libedit library, originally developed on NetBSD. The libedit library is GNU Readline-compatible and is used if libreadline is not found, or if --with-libedit-preferred is used as an option to configure. If you are using a package-based Linux distribution, be aware that you need both the readline and readline-devel packages, if those are separate in your distribution.
Chapter 15. Installation Instructions

- The zlib compression library will be used by default. If you don’t want to use it then you must specify the `--without-zlib` option for `configure`. Using this option disables support for compressed archives in `pg_dump` and `pg_restore`.

The following packages are optional. They are not required in the default configuration, but they are needed when certain build options are enabled, as explained below.

- To build the server programming language PL/Perl you need a full Perl installation, including the `libperl` library and the header files. Since PL/Perl will be a shared library, the `libperl` library must be a shared library also on most platforms. This appears to be the default in recent Perl versions, but it was not in earlier versions, and in any case it is the choice of whomever installed Perl at your site. If you intend to make more than incidental use of PL/Perl, you should ensure that the Perl installation was built with the `usemultiplicity` option enabled (`perl -V` will show whether this is the case).

  If you don’t have the shared library but you need one, a message like this will appear during the build to point out this fact:

  ```
  *** Cannot build PL/Perl because libperl is not a shared library.
  *** You might have to rebuild your Perl installation. Refer to
  *** the documentation for details.
  (If you don’t follow the on-screen output you will merely notice that the PL/Perl library object, `piperl.so` or similar, will not be installed.) If you see this, you will have to rebuild and install Perl manually to be able to build PL/Perl. During the configuration process for Perl, request a shared library.
  ```

- To build the PL/Python server programming language, you need a Python installation with the header files and the distutils module. The distutils module is included by default with Python 1.6 and later; users of earlier versions of Python will need to install it. Since PL/Python will be a shared library, the `libpython` library must be a shared library also on most platforms. This is not the case in a default Python installation. If after building and installing you have a file called `plpython.so` (possibly a different extension), then everything went well. Otherwise you should have seen a notice like this flying by:

  ```
  *** Cannot build PL/Python because libpython is not a shared library.
  *** You might have to rebuild your Python installation. Refer to
  *** the documentation for details.
  That means you have to rebuild (part of) your Python installation to supply this shared library.
  ```

  If you have problems, run Python 2.3 or later’s `configure` using the `--enable-shared` flag. On some operating systems you don’t have to build a shared library, but you will have to convince the PostgreSQL build system of this. Consult the `Makefile` in the `src/pl/plpython` directory for details.

- If you want to build the PL/Tcl procedural language, you of course need a Tcl installation. If you are using a pre-8.4 release of Tcl, ensure that it was built without multithreading support.

- To enable Native Language Support (NLS), that is, the ability to display a program’s messages in a language other than English, you need an implementation of the Gettext API. Some operating systems have this built-in (e.g., Linux, NetBSD, Solaris), for other systems you can download an add-on package from `http://developer.postgresql.org/~petere/bsd-gettext/`. If you are using the Gettext implementation in the GNU C library then you will additionally need the GNU Gettext package for some utility programs. For any of the other implementations you will not need it.

- Kerberos, OpenSSL, OpenLDAP, and/or PAM, if you want to support authentication or encryption using these services.
If you are building from a Git tree instead of using a released source package, or if you want to do server development, you also need the following packages:

- GNU Flex and Bison are needed to build from a Git checkout, or if you changed the actual scanner and parser definition files. If you need them, be sure to get Flex 2.5.4 or later and Bison 1.875 or later. Other yacc programs can sometimes be used, but doing so requires extra effort and is not recommended. Other lex programs will definitely not work.

If you need to get a GNU package, you can find it at your local GNU mirror site (see http://www.gnu.org/order/ftp.html for a list) or at ftp://ftp.gnu.org/gnu/.

Also check that you have sufficient disk space. You will need about 65 MB for the source tree during compilation and about 15 MB for the installation directory. An empty database cluster takes about 25 MB, databases take about five times the amount of space that a flat text file with the same data would take. If you are going to run the regression tests you will temporarily need up to an extra 90 MB. Use the `df` command to check free disk space.

### 15.3. Getting The Source

The PostgreSQL 8.3.23 sources can be obtained by anonymous FTP from ftp://ftp.postgresql.org/pub/source/v8.3.23/postgresql-8.3.23.tar.gz. Other download options can be found on our website: http://www.postgresql.org/download/. After you have obtained the file, unpack it:

```
gunzip postgresql-8.3.23.tar.gz
```

```
tar xf postgresql-8.3.23.tar
```

This will create a directory `postgresql-8.3.23` under the current directory with the PostgreSQL sources. Change into that directory for the rest of the installation procedure.

### 15.4. Upgrading

These instructions assume that your existing installation is under the `/usr/local/pgsql` directory, and that the data area is in `/usr/local/pgsql/data`. Substitute your paths appropriately.

The internal data storage format typically changes in every major release of PostgreSQL. Therefore, if you are upgrading an existing installation that does not have a version number of “8.3.x”, you must back up and restore your data. If you are upgrading from PostgreSQL “8.3.x”, the new version can use your current data files so you should skip the backup and restore steps below because they are unnecessary.

1. If making a backup, make sure that your database is not being updated. This does not affect the integrity of the backup, but the changed data would of course not be included. If necessary, edit the permissions in the file `/usr/local/pgsql/data/pg_hba.conf` (or equivalent) to disallow access from everyone except you.

To back up your database installation, type:

```
pg_dumpall > outputfile
```
Chapter 15. Installation Instructions

If you need to preserve OIDs (such as when using them as foreign keys), then use the -o option when running pg_dumpall.

To make the backup, you can use the pg_dumpall command from the version you are currently running. For best results, however, try to use the pg_dumpall command from PostgreSQL 8.3.23, since this version contains bug fixes and improvements over older versions. While this advice might seem idiosyncratic since you haven’t installed the new version yet, it is advisable to follow it if you plan to install the new version in parallel with the old version. In that case you can complete the installation normally and transfer the data later. This will also decrease the downtime.

2. Shut down the old server:
   
   **pg_ctl stop**
   
   On systems that have PostgreSQL started at boot time, there is probably a start-up file that will accomplish the same thing. For example, on a Red Hat Linux system one might find that
   
   `/etc/rc.d/init.d/postgresql stop`
   
   works.

3. If restoring from backup, rename or delete the old installation directory. It is a good idea to rename the directory, rather than delete it, in case you have trouble and need to revert to it. Keep in mind the directory might consume significant disk space. To rename the directory, use a command like this:

   ```
   mv /usr/local/pgsql /usr/local/pgsql.old
   ```

4. Install the new version of PostgreSQL as outlined in Section 15.5.

5. Create a new database cluster if needed. Remember that you must execute these commands while logged in to the special database user account (which you already have if you are upgrading).

   ```
   /usr/local/pgsql/bin/initdb -D /usr/local/pgsql/data
   ```

6. Restore your previous `pg_hba.conf` and any `postgresql.conf` modifications.

7. Start the database server, again from the special database user account:

   ```
   /usr/local/pgsql/bin/postgres -D /usr/local/pgsql/data
   ```

8. Finally, restore your data from backup with

   ```
   /usr/local/pgsql/bin/psql -d postgres -f outputfile
   ```

   using the new `psql`.

Further discussion appears in Section 24.5, including instructions on how the previous installation can continue running while the new installation is installed.

### 15.5. Installation Procedure

1. Configuration

   The first step of the installation procedure is to configure the source tree for your system and choose the options you would like. This is done by running the `configure` script. For a default installation simply enter

   ```
   ./configure
   ```

   This script will run a number of tests to guess values for various system dependent variables and detect some quirks of your operating system, and finally will create several files in the build tree.
Chapter 15. Installation Instructions

to record what it found. (You can also run configure in a directory outside the source tree if you want to keep the build directory separate.)

The default configuration will build the server and utilities, as well as all client applications and interfaces that require only a C compiler. All files will be installed under /usr/local/pgsql by default.

You can customize the build and installation process by supplying one or more of the following command line options to configure:

```
--prefix=PREFIX
```

Install all files under the directory PREFIX instead of /usr/local/pgsql. The actual files will be installed into various subdirectories; no files will ever be installed directly into the PREFIX directory.

If you have special needs, you can also customize the individual subdirectories with the following options. However, if you leave these with their defaults, the installation will be relocatable, meaning you can move the directory after installation. (The man and doc locations are not affected by this.)

For relocatable installs, you might want to use configure’s --disable-rpath option. Also, you will need to tell the operating system how to find the shared libraries.

```
--exec-prefix=EXEC-PREFIX
```

You can install architecture-dependent files under a different prefix, EXEC-PREFIX, than what PREFIX was set to. This can be useful to share architecture-independent files between hosts. If you omit this, then EXEC-PREFIX is set equal to PREFIX and both architecture-dependent and independent files will be installed under the same tree, which is probably what you want.

```
--bindir=DIRECTORY
```

Specifies the directory for executable programs. The default is EXEC-PREFIX/bin, which normally means /usr/local/pgsql/bin.

```
--datadir=DIRECTORY
```

Sets the directory for read-only data files used by the installed programs. The default is PREFIX/share. Note that this has nothing to do with where your database files will be placed.

```
--sysconfdir=DIRECTORY
```

The directory for various configuration files, PREFIX/etc by default.

```
--libdir=DIRECTORY
```

The location to install libraries and dynamically loadable modules. The default is EXEC-PREFIX/lib.

```
--includedir=DIRECTORY
```

The directory for installing C and C++ header files. The default is PREFIX/include.

```
--mandir=DIRECTORY
```

The man pages that come with PostgreSQL will be installed under this directory, in their respective manx subdirectories. The default is PREFIX/man.
**--with-docdir=DIRECTORY**

Documentation files, except "man" pages, will be installed into this directory. The default is `PREFIX/doc`. If the option `--without-docdir` is specified, the documentation will not be installed by `make install`. This is intended for packaging scripts that have special methods for installing documentation.

**Note:** Care has been taken to make it possible to install PostgreSQL into shared installation locations (such as `/usr/local/include`) without interfering with the namespace of the rest of the system. First, the string "/postgresql" is automatically appended to `datadir`, `sysconfdir`, and `docdir`, unless the fully expanded directory name already contains the string "postgresql" or "pgsql". For example, if you choose `/usr/local` as prefix, the documentation will be installed in `/usr/local/doc/postgresql`, but if the prefix is `/opt/postgres`, then it will be in `/opt/postgres/doc`. The public C header files of the client interfaces are installed into `includedir` and are namespace-clean. The internal header files and the server header files are installed into private directories under `includedir`. See the documentation of each interface for information about how to get at the its header files. Finally, a private subdirectory will also be created, if appropriate, under `libdir` for dynamically loadable modules.

**--with-includes=DIRECTORIES**

`DIRECTORIES` is a colon-separated list of directories that will be added to the list the compiler searches for header files. If you have optional packages (such as GNU Readline) installed in a non-standard location, you have to use this option and probably also the corresponding `--with-libraries` option.

Example: `--with-includes=/opt/gnu/include:/usr/sup/include`.

**--with-libraries=DIRECTORIES**

`DIRECTORIES` is a colon-separated list of directories to search for libraries. You will probably have to use this option (and the corresponding `--with-includes` option) if you have packages installed in non-standard locations.

Example: `--with-libraries=/opt/gnu/lib:/usr/sup/lib`.

**--enable-nls[=LANGUAGES]**

Enables Native Language Support (NLS), that is, the ability to display a program’s messages in a language other than English. `LANGUAGES` is a space-separated list of codes of the languages that you want supported, for example `--enable-nls='de fr'`. (The intersection between your list and the set of actually provided translations will be computed automatically.) If you do not specify a list, then all available translations are installed.

To use this option, you will need an implementation of the Gettext API; see above.

**--with-pgport=NUMBER**

Set `NUMBER` as the default port number for server and clients. The default is 5432. The port can always be changed later on, but if you specify it here then both server and clients will have the same default compiled in, which can be very convenient. Usually the only good reason to select a non-default value is if you intend to run multiple PostgreSQL servers on the same machine.
Chapter 15. Installation Instructions

--with-perl
    Build the PL/Perl server-side language.

--with-python
    Build the PL/Python server-side language.

--with-tcl
    Build the PL/Tcl server-side language.

--with-tclconfig=DIRECTORY
    Tcl installs the file tclConfig.sh, which contains configuration information needed to
    build modules interfacing to Tcl. This file is normally found automatically at a well-known
    location, but if you want to use a different version of Tcl you can specify the directory in
    which to look for it.

--with-gssapi
    Build with support for GSSAPI authentication. On many systems, the GSSAPI (usually
    a part of the Kerberos installation) system is not installed in a location that is searched by
    default (e.g., /usr/include, /usr/lib), so you must use the options --with-includes
    and --with-libraries in addition to this option. configure will check for the required
    header files and libraries to make sure that your GSSAPI installation is sufficient before
    proceeding.

--with-krb5
    Build with support for Kerberos 5 authentication. On many systems, the Kerberos system is
    not installed in a location that is searched by default (e.g., /usr/include, /usr/lib), so
    you must use the options --with-includes and --with-libraries in addition to this
    option. configure will check for the required header files and libraries to make sure that
    your Kerberos installation is sufficient before proceeding.

--with-krb-srvnam=NAME
    The default name of the Kerberos service principal (also used by GSSAPI). postgres is the
    default. There’s usually no reason to change this unless you have a Windows environment,
    in which case it must be set to uppercase POSTGRES.

--with-openssl
    Build with support for SSL (encrypted) connections. This requires the OpenSSL package to
    be installed. configure will check for the required header files and libraries to make sure
    that your OpenSSL installation is sufficient before proceeding.

--with-pam
    Build with PAM (Pluggable Authentication Modules) support.

--with-ldap
    Build with LDAP support for authentication and connection parameter lookup (see Section
    30.15 and Section 21.2.7 for more information). On Unix, this requires the OpenLDAP
    package to be installed. configure will check for the required header files and libraries to
    make sure that your OpenLDAP installation is sufficient before proceeding. On Windows,
    the default WinLDAP library is used.

--without-readline
    Prevents use of the Readline library (and libedit as well). This option disables command-line
    editing and history in psql, so it is not recommended.
--with-libedit-preferred
Favors the use of the BSD-licensed libedit library rather than GPL-licensed Readline. This option is significant only if you have both libraries installed; the default in that case is to use Readline.

--with-bonjour
Build with Bonjour support. This requires Bonjour support in your operating system. Recommended on Mac OS X.

--with-ossp-uuid
Use the OSSP UUID library\(^1\) when building contrib/uuid-oss. The library provides functions to generate UUIDs.

--with-libxml
Build with libxml (enables SQL/XML support). Libxml version 2.6.23 or later is required for this feature.

Libxml installs a program xml2-config that can be used to detect the required compiler and linker options. PostgreSQL will use it automatically if found. To specify a libxml installation at an unusual location, you can either set the environment variable XML2_CONFIG to point to the xml2-config program belonging to the installation, or use the options --with-includes and --with-libraries.

--with-libxslt
Use libxslt when building contrib/xml2. contrib/xml2 relies on this library to perform XSL transformations of XML.

--enable-integer-datetimes
Use 64-bit integer storage for datetimes and intervals, rather than the default floating-point storage. This reduces the range of representable values but guarantees microsecond precision across the full range (see Section 8.5 for more information).

--disable-spinlocks
Allow the build to succeed even if PostgreSQL has no CPU spinlock support for the platform. The lack of spinlock support will result in poor performance; therefore, this option should only be used if the build aborts and informs you that the platform lacks spinlock support. If this option is required to build PostgreSQL on your platform, please report the problem to the PostgreSQL developers.

--enable-thread-safety
Make the client libraries thread-safe. This allows concurrent threads in libpq and ECPG programs to safely control their private connection handles. This option requires adequate threading support in your operating system.

--with-system-tzdata=DIRECTORY
PostgreSQL includes its own time zone database, which it requires for date and time operations. This time zone database is in fact compatible with the \textit{zic} time zone database provided by many operating systems such as FreeBSD, Linux, and Solaris, so it would be redundant to install it again. When this option is used, the system-supplied time zone database in \textit{DIRECTORY} is used instead of the one included in the PostgreSQL source distribution. \textit{DIRECTORY} must be specified as an absolute path. /usr/share/zoneinfo is a likely directory on some operating systems. Note that the installation routine will not detect

\(^1\) http://www.ossp.org/pkg/lib/uuid/
Chapter 15. Installation Instructions

mismatching or erroneous time zone data. If you use this option, you are advised to run the regression tests to verify that the time zone data you have pointed to works correctly with PostgreSQL.

This option is mainly aimed at binary package distributors who know their target operating system well. The main advantage of using this option is that the PostgreSQL package won’t need to be upgraded whenever any of the many local daylight-saving time rules change. Another advantage is that PostgreSQL can be cross-compiled more straightforwardly if the time zone database files do not need to be built during the installation.

--without-zlib
Prevents use of the Zlib library. This disables support for compressed archives in pg_dump and pg_restore. This option is only intended for those rare systems where this library is not available.

--enable-debug
Compiles all programs and libraries with debugging symbols. This means that you can run the programs through a debugger to analyze problems. This enlarges the size of the installed executables considerably, and on non-GCC compilers it usually also disables compiler optimization, causing slowdowns. However, having the symbols available is extremely helpful for dealing with any problems that might arise. Currently, this option is recommended for production installations only if you use GCC. But you should always have it on if you are doing development work or running a beta version.

--enable-profiling
If using GCC, all programs and libraries are compiled so they can be profiled. On backend exit, a subdirectory will be created that contains the gmon.out file for use in profiling. This option is for use only with GCC and when doing development work.

--enable-cassert
 Enables assertion checks in the server, which test for many “cannot happen” conditions. This is invaluable for code development purposes, but the tests can slow down the server significantly. Also, having the tests turned on won’t necessarily enhance the stability of your server! The assertion checks are not categorized for severity, and so what might be a relatively harmless bug will still lead to server restarts if it triggers an assertion failure. This option is not recommended for production use, but you should have it on for development work or when running a beta version.

--enable-depend
Enables automatic dependency tracking. With this option, the makefiles are set up so that all affected object files will be rebuilt when any header file is changed. This is useful if you are doing development work, but is just wasted overhead if you intend only to compile once and install. At present, this option will work only if you use GCC.

--enable-dtrace
Compiles with support for the dynamic tracing tool DTrace. Operating system support for DTrace is currently only available in Solaris.

To point to the dtrace program, the environment variable DTRACE can be set. This will often be necessary because dtrace is typically installed under /usr/sbin, which might not be in the path. Additional command-line options for the dtrace program can be specified in the environment variable DTRACEFLAGS.

To include DTrace support in a 64-bit binary, specify DTRACEFLAGS="-64" to configure. For example, using the GCC compiler:
Chapter 15. Installation Instructions

./configure CC='gcc -m64' --enable-dtrace DTRACEFLAGS='--64' ...

Using Sun’s compiler:

./configure CC='/opt/SUNWspro/bin/cc -xtarget=native64' --enable-dtrace DTRACEFLAGS='--64' ...

If you prefer a C compiler different from the one configure picks, you can set the environment variable CC to the program of your choice. By default, configure will pick gcc if available, else the platform’s default (usually cc). Similarly, you can override the default compiler flags if needed with the CFLAGS variable.

You can specify environment variables on the configure command line, for example:

./configure CC=/opt/bin/gcc CFLAGS='-O2 -pipe'

Here is a list of the significant variables that can be set in this manner:

CC
   C compiler

CFLAGS
   options to pass to the C compiler

CPP
   C preprocessor

CPPFLAGS
   options to pass to the C preprocessor

DTRACE
   location of the dtrace program

DTRACEFLAGS
   options to pass to the dtrace program

LDFLAGS
   options to pass to the link editor

LDFLAGS_SL
   linker options for shared library linking

MSGFMT
   msgfmt program for native language support

PERL
   Full path to the Perl interpreter. This will be used to determine the dependencies for building PL/Perl.

PYTHON
   Full path to the Python interpreter. This will be used to determine the dependencies for building PL/Python.

TCLSH
   Full path to the Tcl interpreter. This will be used to determine the dependencies for building PL/Tcl.
Chapter 15. Installation Instructions

XML2_CONFIG

xml2-config program used to locate the libxml installation.

YACC

Yacc program (bison -y if using Bison)

2. Build

To start the build, type

```
gmake
```

(Remember to use GNU make.) The build will take a few minutes depending on your hardware. The last line displayed should be

```
All of PostgreSQL is successfully made. Ready to install.
```

3. Regression Tests

If you want to test the newly built server before you install it, you can run the regression tests at this point. The regression tests are a test suite to verify that PostgreSQL runs on your machine in the way the developers expected it to. Type

```
gmake check
```

(This won’t work as root; do it as an unprivileged user.) Chapter 29 contains detailed information about interpreting the test results. You can repeat this test at any later time by issuing the same command.

4. Installing The Files

**Note:** If you are upgrading an existing system and are going to install the new files over the old ones, be sure to back up your data and shut down the old server before proceeding, as explained in Section 15.4 above.

To install PostgreSQL enter

```
gmake install
```

This will install files into the directories that were specified in step 1. Make sure that you have appropriate permissions to write into that area. Normally you need to do this step as root. Alternatively, you could create the target directories in advance and arrange for appropriate permissions to be granted.

You can use `gmake install-strip` instead of `gmake install` to strip the executable files and libraries as they are installed. This will save some space. If you built with debugging support, stripping will effectively remove the debugging support, so it should only be done if debugging is no longer needed. `install-strip` tries to do a reasonable job saving space, but it does not have perfect knowledge of how to strip every unneeded byte from an executable file, so if you want to save all the disk space you possibly can, you will have to do manual work.

The standard installation provides all the header files needed for client application development as well as for server-side program development, such as custom functions or data types written in C. (Prior to PostgreSQL 8.0, a separate `gmake install-all-headers` command was needed for the latter, but this step has been folded into the standard install.)

**Client-only installation:** If you want to install only the client applications and interface libraries, then you can use these commands:

```
gmake -C src/bin install
```

322
Chapter 15. Installation Instructions

```
gmake -C src/include install

gmake -C src/interfaces install

gmake -C doc install
```

src/bin has a few binaries for server-only use, but they are small.

Registering eventlog on Windows: To register a Windows eventlog library with the operating system, issue this command after installation:

```
regsvr32 pgsql_library_directory/pgevent.dll
```

This creates registry entries used by the event viewer.

Uninstallation: To undo the installation use the command `gmake uninstall`. However, this will not remove any created directories.

Cleaning: After the installation you can make room by removing the built files from the source tree with the command `gmake clean`. This will preserve the files made by the `configure` program, so that you can rebuild everything with `gmake` later on. To reset the source tree to the state in which it was distributed, use `gmake distclean`. If you are going to build for several platforms within the same source tree you must do this and re-configure for each build. (Alternatively, use a separate build tree for each platform, so that the source tree remains unmodified.)

If you perform a build and then discover that your `configure` options were wrong, or if you change anything that `configure` investigates (for example, software upgrades), then it’s a good idea to do `gmake distclean` before reconfiguring and rebuilding. Without this, your changes in configuration choices might not propagate everywhere they need to.

### 15.6. Post-Installation Setup

15.6.1. Shared Libraries

On some systems that have shared libraries (which most systems do) you need to tell your system how to find the newly installed shared libraries. The systems on which this is not necessary include BSD/OS, FreeBSD, HP-UX, IRIX, Linux, NetBSD, OpenBSD, Tru64 UNIX (formerly Digital UNIX), and Solaris.

The method to set the shared library search path varies between platforms, but the most widely usable method is to set the environment variable `LD_LIBRARY_PATH` like so: In Bourne shells (`sh`, `ksh`, `bash`, `zsh`):

```
LD_LIBRARY_PATH=/usr/local/pgsql/lib
export LD_LIBRARY_PATH
```

or in `csh` or `tcsh`:

```
setenv LD_LIBRARY_PATH /usr/local/pgsql/lib
```

Replace `/usr/local/pgsql/lib` with whatever you set `--libdir` to in step 1. You should put these commands into a shell start-up file such as `/etc/profile` or `~/.bash_profile`. Some good information about the caveats associated with this method can be found at http://www.visi.com/~barr/ldpath.html.

On some systems it might be preferable to set the environment variable `LD_RUN_PATH` before building.
Chapter 15. Installation Instructions

On Cygwin, put the library directory in the PATH or move the .dll files into the bin directory.

If in doubt, refer to the manual pages of your system (perhaps ld.so or rld). If you later on get a message like

```
psql: error in loading shared libraries
libpq.so.2.1: cannot open shared object file: No such file or directory
```

then this step was necessary. Simply take care of it then.

If you are on BSD/OS, Linux, or SunOS 4 and you have root access you can run:

```
/sbin/ldconfig /usr/local/pgsql/lib
```

(or equivalent directory) after installation to enable the run-time linker to find the shared libraries faster. Refer to the manual page of ldconfig for more information. On FreeBSD, NetBSD, and OpenBSD the command is:

```
/sbin/ldconfig -m /usr/local/pgsql/lib
```

instead. Other systems are not known to have an equivalent command.

15.6.2. Environment Variables

If you installed into /usr/local/pgsql or some other location that is not searched for programs by default, you should add /usr/local/pgsql/bin (or whatever you set --bindir to in step 1) into your PATH. Strictly speaking, this is not necessary, but it will make the use of PostgreSQL much more convenient.

To do this, add the following to your shell start-up file, such as ~/.bash_profile (or /etc/profile, if you want it to affect every user):

```
PATH=/usr/local/pgsql/bin:$PATH
export PATH
```

If you are using csh or tcsh, then use this command:

```
set path = ( /usr/local/pgsql/bin $path )
```

To enable your system to find the man documentation, you need to add lines like the following to a shell start-up file unless you installed into a location that is searched by default:

```
MANPATH=/usr/local/pgsql/man:$MANPATH
export MANPATH
```

The environment variables PGHOST and PGPORT specify to client applications the host and port of the database server, overriding the compiled-in defaults. If you are going to run client applications remotely then it is convenient if every user that plans to use the database sets PGHOST. This is not required, however: the settings can be communicated via command line options to most client programs.
15.7. Supported Platforms

A platform (that is, a CPU architecture and operating system combination) is considered supported by the PostgreSQL development community if the code contains provisions to work on that platform and it has recently been verified to build and pass its regression tests on that platform. Currently, most testing of platform compatibility is done automatically by test machines in the PostgreSQL Build Farm\(^2\). If you are interested in using PostgreSQL on a platform that is not represented in the build farm, but on which the code works or can be made to work, you are strongly encouraged to set up a build farm member machine so that continued compatibility can be assured.

In general, PostgreSQL can be expected to work on these CPU architectures: x86, x86_64, IA64, PowerPC, PowerPC 64, S/390, S/390x, Sparc, Sparc 64, Alpha, ARM, MIPS, MIPSEL, M68K, and PA-RISC. Code support exists for M32R, NS32K, and VAX, but these architectures are not known to have been tested recently. It is often possible to build on an unsupported CPU type by configuring with `--disable-spinlocks`, but performance will be poor.

PostgreSQL can be expected to work on these operating systems: Linux (all recent distributions), Windows (Win2000 SP4 and later), FreeBSD, OpenBSD, NetBSD, Mac OS X, AIX, HP/UX, IRIX, Solaris, Tru64 Unix, and UnixWare. Other Unix-like systems may also work but are not currently being tested. In most cases, all CPU architectures supported by a given operating system will work. Look in the `doc/` directory of the source distribution to see if there is a FAQ document specific to your operating system, particularly if using an older system.

If you have installation problems on a platform that is known to be supported according to recent build farm results, please report it to `<pgsql-bugs@postgresql.org>`. If you are interested in porting PostgreSQL to a new platform, `<pgsql-hackers@postgresql.org>` is the appropriate place to discuss that.

\(^2\) [http://buildfarm.postgresql.org/](http://buildfarm.postgresql.org/)
Chapter 16. Installation on Windows

It is recommended that most users download the binary distribution for Windows, available as a Windows Installer package from the PostgreSQL website. Building from source is only intended for people developing PostgreSQL or extensions.

There are several different ways of building PostgreSQL on Windows. The complete system can be built using MinGW or Visual C++ 2005. It can also be built for older versions of Windows using Cygwin. Finally, the client access library (libpq) can be built using Visual C++ 7.1 or Borland C++ for compatibility with statically linked applications built using these tools.

Building using MinGW or Cygwin uses the normal build system, see Chapter 15 and the FAQs in doc/FAQ_MINGW and do/FAQ_CYGWIN. Note that Cygwin is not recommended, and should only be used for older versions of Windows where the native build does not work, such as Windows 98.

The tools for building using Visual C++ 2005, are in the src/tools/msvc directory. When building, make sure there are no tools from MinGW or Cygwin present in your system PATH. Also, make sure you have all the required Visual C++ tools available in the PATH, usually by starting a Visual Studio Command Prompt and running the commands from there. All commands should be run from the src\tools\msvc directory.

Before you build, edit the file config.pl to reflect the configuration options you want set, including the paths to libraries used. If you need to set any other environment variables, create a file called buildenv.pl and put the required commands there. For example, to add the path for bison when it’s not in the PATH, create a file containing:

```
$ENV{PATH}=$ENV{PATH} . ';c:\some\where\bison\bin';
```

16.1.1. Requirements

PostgreSQL will build using either the professional versions (any edition) or the free Express edition of Visual Studio 2005. The following additional products are required to build the complete package. Use the config.pl file to specify which directories the libraries are available in.

ActiveState Perl

ActiveState Perl is required to run the build generation scripts. MinGW or Cygwin Perl will not work. It must also be present in the PATH. Binaries can be downloaded from http://www.activestate.com (Note: version 5.8 or later is required, the free Standard Distribution is sufficient).

ActiveState TCL

Required for building PL/TCL (Note: version 8.4 is required, the free Standard Distribution is sufficient).
Chapter 16. Installation on Windows

Bison and Flex

Bison and Flex are required to build from Git, but not required when building from a release file. Note that only Bison 1.875 or versions 2.2 and later will work. Bison and Flex can be downloaded from http://gnuwin32.sourceforge.net.

Diff

Diff is required to run the regression tests, and can be downloaded from http://gnuwin32.sourceforge.net.

Gettext

Gettext is required to build with NLS support, and can be downloaded from http://gnuwin32.sourceforge.net. Note that binaries, dependencies and developer files are all needed.

Microsoft Platform SDK

It is recommended that you upgrade to the latest available version of the Microsoft Platform SDK, available for download from http://www.microsoft.com/downloads/.

MIT Kerberos

libxml2 and libxslt

Required for XML support. Binaries can be downloaded from http://zlatkovic.com/pub/libxml or source from http://xmlsoft.org. Note that libxml2 requires iconv, which is available from the same download location.

openssl

ossp-uuid

Required for UUID-OSSP support (contrib only). Source can be downloaded from http://www.ossp.org/pkg/lib/uuid/.

Python

zlib

Required for compression support in pg_dump and pg_restore. Binaries can be downloaded from http://www.zlib.net.

16.1.2. Building

To build all of PostgreSQL in release configuration (the default), run the command:

\texttt{build}

To build all of PostgreSQL in debug configuration, run the command:
Chapter 16. Installation on Windows

To build just a single project, for example psql, run the commands:

```bash
build psql
build DEBUG psql
```

To change the default build configuration to debug, put the following in the `buildenv.pl` file:

```perl
$ENV{CONFIG}="Debug";
```

It is also possible to build from inside the Visual Studio GUI. In this case, you need to run:

```bash
perl mkvcbuild.pl
```

from the command prompt, and then open the generated `pgsql.sln` (in the root directory of the source tree) in Visual Studio.

### 16.1.3. Cleaning and installing

Most of the time, the automatic dependency tracking in Visual Studio will handle changed files. But if there have been large changes, you may need to clean the installation. To do this, simply run the `clean.bat` command, which will automatically clean out all generated files. You can also run it with the `dist` parameter, in which case it will behave like `make distclean` and remove the flex/bison output files as well.

By default, all files are written into a subdirectory of the `debug` or `release` directories. To install these files using the standard layout, and also generate the files required to initialize and use the database, run the command:

```bash
perl install.pl c:\destination\directory
```

### 16.1.4. Running the regression tests

To run the regression tests, make sure you have completed the build of all required parts first. Also, make sure that the DLLs required to load all parts of the system (such as the Perl and Python DLLs for the procedural languages) are present in the system path. If they are not, set it through the
Chapter 16. Installation on Windows

buildenv.pl file. To run the tests, run one of the following commands from the src\tools\msvc directory:

- vcregress check
- vcregress installcheck
- vcregress plcheck
- vcregress contribcheck

To change the schedule used (default is the parallel), append it to the command line like:

- vcregress check serial

For more information about the regression tests, see Chapter 29.

16.1.5. Building the documentation

Building the PostgreSQL documentation in HTML format requires several tools and files. Create a root directory for all these files, and store them in the subdirectories in the list below.

OpenJade 1.3.1-2

Download from http://sourceforge.net/project/downloading.php?groupname=openjade&filename=openjade-1_3_1-2-bin.zip and uncompress in the subdirectory openjade-1.3.1.

DocBook DTD 4.2

DocBook DSSSL 1.79

ISO character entities

Edit the buildenv.pl file, and add a variable for the location of the root directory, for example:

$ENV{DOCROOT}='c:\docbook';

To build the documentation, run the command builddoc.bat. Note that this will actually run the build twice, in order to generate the indexes. The generated HTML files will be in doc\src\sgml.
16.2. Building libpq with Visual C++ or Borland C++

Using Visual C++ 7.1-8.0 or Borland C++ to build libpq is only recommended if you need a version with different debug/release flags, or if you need a static library to link into an application. For normal use the MinGW or Visual Studio 2005 version is recommended.

To build the libpq client library using Visual Studio 7.1 or later, change into the src directory and type the command

```
nmake /f win32.mak
```

To build a 64-bit version of the libpq client library using Visual Studio 8.0 or later, change into the src directory and type in the command

```
nmake /f win32.mak CPU=AMD64
```

See the win32.mak file for further details about supported variables.

To build the libpq client library using Borland C++, change into the src directory and type the command

```
make -N -DCFG=Release /f bcc32.mak
```

16.2.1. Generated files

The following files will be built:

```
interfaces\libpq\Release\libpq.dll
```

The dynamically linkable frontend library

```
interfaces\libpq\Release\libpqdll.lib
```

Import library to link your programs to libpq.dll

```
interfaces\libpq\Release\libpq.lib
```

Static version of the frontend library

Normally you do not need to install any of the client files. You should place the libpq.dll file in the same directory as your applications executable file. Do not install libpq.dll into your Windows, System or System32 directory unless absolutely necessary. If this file is installed using a setup program, it should be installed with version checking using the VERSIONINFO resource included in the file, to ensure that a newer version of the library is not overwritten.

If you are planning to do development using libpq on this machine, you will have to add the src\include and src\interfaces\libpq subdirectories of the source tree to the include path in your compiler’s settings.

To use the library, you must add the libpqdll.lib file to your project. (In Visual C++, just right-click on the project and choose to add it.)
Chapter 17. Operating System Environment

This chapter discusses how to set up and run the database server and its interactions with the operating system.

17.1. The PostgreSQL User Account

As with any other server daemon that is accessible to the outside world, it is advisable to run PostgreSQL under a separate user account. This user account should only own the data that is managed by the server, and should not be shared with other daemons. (For example, using the user nobody is a bad idea.) It is not advisable to install executables owned by this user because compromised systems could then modify their own binaries.

To add a Unix user account to your system, look for a command useradd or adduser. The user name postgres is often used, and is assumed throughout this book, but you can use another name if you like.

17.2. Creating a Database Cluster

Before you can do anything, you must initialize a database storage area on disk. We call this a database cluster. (SQL uses the term catalog cluster.) A database cluster is a collection of databases that is managed by a single instance of a running database server. After initialization, a database cluster will contain a database named postgres, which is meant as a default database for use by utilities, users and third party applications. The database server itself does not require the postgres database to exist, but many external utility programs assume it exists. Another database created within each cluster during initialization is called template1. As the name suggests, this will be used as a template for subsequently created databases; it should not be used for actual work. (See Chapter 20 for information about creating new databases within a cluster.)

In file system terms, a database cluster will be a single directory under which all data will be stored. We call this the data directory or data area. It is completely up to you where you choose to store your data. There is no default, although locations such as /usr/local/pgsql/data or /var/lib/pgsql/data are popular. To initialize a database cluster, use the command initdb, which is installed with PostgreSQL. The desired file system location of your database cluster is indicated by the -D option, for example

$ initdb -D /usr/local/pgsql/data

Note that you must execute this command while logged into the PostgreSQL user account, which is described in the previous section.

Tip: As an alternative to the -D option, you can set the environment variable PGDATA.

initdb will attempt to create the directory you specify if it does not already exist. It is likely that it will not have the permission to do so (if you followed our advice and created an unprivileged account). In that case you should create the directory yourself (as root) and change the owner to be the PostgreSQL user. Here is how this might be done:

root# mkdir /usr/local/pgsql/data
Chapter 17. Operating System Environment

root# chown postgres /usr/local/pgsql/data
root# su postgres
postgres$ initdb -D /usr/local/pgsql/data

initdb will refuse to run if the data directory looks like it has already been initialized.

Because the data directory contains all the data stored in the database, it is essential that it be secured from unauthorized access. initdb therefore revokes access permissions from everyone but the PostgreSQL user.

However, while the directory contents are secure, the default client authentication setup allows any local user to connect to the database and even become the database superuser. If you do not trust other local users, we recommend you use one of initdb’s -W, --pwprompt or --pwfile options to assign a password to the database superuser. Also, specify -A md5 or -A password so that the default trust authentication mode is not used; or modify the generated pg_hba.conf file after running initdb, before you start the server for the first time. (Other reasonable approaches include using ident authentication or file system permissions to restrict connections. See Chapter 21 for more information.)

initdb also initializes the default locale for the database cluster. Normally, it will just take the locale settings in the environment and apply them to the initialized database. It is possible to specify a different locale for the database; more information about that can be found in Section 22.1. The sort order used within a particular database cluster is set by initdb and cannot be changed later, short of dumping all data, rerunning initdb, and reloading the data. There is also a performance impact for using locales other than C or POSIX. Therefore, it is important to make this choice correctly the first time.

initdb also sets the default character set encoding for the database cluster. Normally this should be chosen to match the locale setting. For details see Section 22.2.

17.2.1. Network File Systems

Many installations create database clusters on network file systems. Sometimes this is done directly via NFS, or by using a Network Attached Storage (NAS) device that uses NFS internally. PostgreSQL does nothing special for NFS file systems, meaning it assumes NFS behaves exactly like locally-connected drives (DAS, Direct Attached Storage). If client and server NFS implementations have non-standard semantics, this can cause reliability problems (see http://www.time-travellers.org/shane/papers/NFS_considered_harmful.html). Specifically, delayed (asynchronous) writes to the NFS server can cause reliability problems; if possible, mount NFS file systems synchronously (without caching) to avoid this. (Storage Area Networks (SAN) use a low-level communication protocol rather than NFS.)

17.3. Starting the Database Server

Before anyone can access the database, you must start the database server. The database server program is called postgres. The postgres program must know where to find the data it is supposed to use. This is done with the -D option. Thus, the simplest way to start the server is:

$ postgres -D /usr/local/pgsql/data
which will leave the server running in the foreground. This must be done while logged into the Post- 
greSQL user account. Without -D, the server will try to use the data directory named by the environ-
ment variable PGDATA. If that variable is not provided either, it will fail.

Normally it is better to start `postgres` in the background. For this, use the usual shell syntax:

```
$ postgres -D /usr/local/pgsql/data >logfile 2>&1 &
```

It is important to store the server’s stdout and stderr output somewhere, as shown above. It will help 
for auditing purposes and to diagnose problems. (See Section 23.3 for a more thorough discussion of 
log file handling.)

The `postgres` program also takes a number of other command-line options. For more information, 
see the `postgres` reference page and Chapter 18 below.

This shell syntax can get tedious quickly. Therefore the wrapper program `pg_ctl` is provided to sim-
plify some tasks. For example:

```
pg_ctl start -l logfile
```

will start the server in the background and put the output into the named log file. The -D option has 
the same meaning here as for `postgres`. `pg_ctl` is also capable of stopping the server.

Normally, you will want to start the database server when the computer boots. Autostart 
scripts are operating-system-specific. There are a few distributed with PostgreSQL in the 
`contrib/start-scripts` directory. Installing one will require root privileges.

Different systems have different conventions for starting up daemons at boot time. Many systems have 
a file `/etc/rc.local` or `/etc/rc.d/rc.local`. Others use `rc.d` directories. Whatever you do, 
the server must be run by the PostgreSQL user account and not by root or any other user. Therefore 
you probably should form your commands using `su postgres -c '...'. For example:

```
su postgres -c 'pg_ctl start -D /usr/local/pgsql/data -l serverlog'
```

Here are a few more operating-system-specific suggestions. (In each case be sure to use the proper 
installation directory and user name where we show generic values.)

- For FreeBSD, look at the file `contrib/start-scripts/freebsd` in the PostgreSQL source 
distribution.
- On OpenBSD, add the following lines to the file `/etc/rc.local`:

  ```
  if [ -x /usr/local/pgsql/bin/pg_ctl -a -x /usr/local/pgsql/bin/postgres ]; then
  su -l postgres -c '/usr/local/pgsql/bin/pg_ctl start -s -l /var/postgresql/log -D /usr/local/pgsql/data'
  echo -n ' postgresql'
  fi
  ```
- On Linux systems either add

  ```
  /usr/local/pgsql/bin/pg_ctl start -l logfile -D /usr/local/pgsql/data 
  ```
  
  to `/etc/rc.d/rc.local` or look at the file `contrib/start-scripts/linux` in the Post-
  greSQL source distribution.
- On NetBSD, use either the FreeBSD or Linux start scripts, depending on preference.
- On Solaris, create a file called `/etc/init.d/postgresql` that contains the following line:

  ```
  su - postgres -c "/usr/local/pgsql/bin/pg_ctl start -l logfile -D /usr/local/pgsql/data"
  ```

  Then, create a symbolic link to it in `/etc/rc3.d/S99postgresql`. 

While the server is running, its PID is stored in the file `postmaster.pid` in the data directory. This is used to prevent multiple server instances from running in the same data directory and can also be used for shutting down the server.

### 17.3.1. Server Start-up Failures

There are several common reasons the server might fail to start. Check the server’s log file, or start it by hand (without redirecting standard output or standard error) and see what error messages appear. Below we explain some of the most common error messages in more detail.

**LOG:** could not bind IPv4 socket: Address already in use  
**HINT:** Is another postmaster already running on port 5432? If not, wait a few seconds and retry.  
**FATAL:** could not create TCP/IP listen socket

This usually means just what it suggests: you tried to start another server on the same port where one is already running. However, if the kernel error message is not `Address already in use` or some variant of that, there might be a different problem. For example, you might try to start a server on a reserved port number:

```
$ postgres -p 666  
```

**LOG:** could not bind IPv4 socket: Permission denied  
**HINT:** Is another postmaster already running on port 666? If not, wait a few seconds and retry.  
**FATAL:** could not create TCP/IP listen socket

A message like

**FATAL:** could not create shared memory segment: Invalid argument  
**DETAIL:** Failed system call was `shmget(key=5440001, size=4011376640, 03600)`.

probably means your kernel’s limit on the size of shared memory is smaller than the work area PostgreSQL is trying to create (4011376640 bytes in this example). Or it could mean that you do not have System-V-style shared memory support configured into your kernel at all. As a temporary workaround, you can try starting the server with a smaller-than-normal number of buffers (shared_buffers). You will eventually want to reconfigure your kernel to increase the allowed shared memory size. You might also see this message when trying to start multiple servers on the same machine, if their total space requested exceeds the kernel limit.

An error like

**FATAL:** could not create semaphores: No space left on device  
**DETAIL:** Failed system call was `semget(5440126, 17, 03600)`.

does not mean you’ve run out of disk space. It means your kernel’s limit on the number of System V semaphores is smaller than the number PostgreSQL wants to create. As above, you might be able to work around the problem by starting the server with a reduced number of allowed connections (max_connections), but you’ll eventually want to increase the kernel limit.

If you get an “illegal system call” error, it is likely that shared memory or semaphores are not supported in your kernel at all. In that case your only option is to reconfigure the kernel to enable these features.

Details about configuring System V IPC facilities are given in Section 17.4.1.
17.3.2. Client Connection Problems

Although the error conditions possible on the client side are quite varied and application-dependent, a few of them might be directly related to how the server was started up. Conditions other than those shown below should be documented with the respective client application.

```
psql: could not connect to server: Connection refused
    Is the server running on host "server.joe.com" and accepting
    TCP/IP connections on port 5432?
```

This is the generic “I couldn’t find a server to talk to” failure. It looks like the above when TCP/IP communication is attempted. A common mistake is to forget to configure the server to allow TCP/IP connections.

Alternatively, you’ll get this when attempting Unix-domain socket communication to a local server:

```
psql: could not connect to server: No such file or directory
    Is the server running locally and accepting
    connections on Unix domain socket "/tmp/.s.PGSQL.5432"?
```

The last line is useful in verifying that the client is trying to connect to the right place. If there is in fact no server running there, the kernel error message will typically be either Connection refused or No such file or directory, as illustrated. (It is important to realize that Connection refused in this context does not mean that the server got your connection request and rejected it. That case will produce a different message, as shown in Section 21.3.) Other error messages such as Connection timed out might indicate more fundamental problems, like lack of network connectivity.

17.4. Managing Kernel Resources

A large PostgreSQL installation can quickly exhaust various operating system resource limits. (On some systems, the factory defaults are so low that you don’t even need a really “large” installation.) If you have encountered this kind of problem, keep reading.

17.4.1. Shared Memory and Semaphores

Shared memory and semaphores are collectively referred to as “System V IPC” (together with message queues, which are not relevant for PostgreSQL). Almost all modern operating systems provide these features, but not all of them have them turned on or sufficiently sized by default, especially systems with BSD heritage. (On Windows, PostgreSQL provides its own replacement implementation of these facilities, and so most of this section can be disregarded.)

The complete lack of these facilities is usually manifested by an Illegal system call error upon server start. In that case there’s nothing left to do but to reconfigure your kernel. PostgreSQL won’t work without them.

When PostgreSQL exceeds one of the various hard IPC limits, the server will refuse to start and should leave an instructive error message describing the problem encountered and what to do about it. (See also Section 17.3.1.) The relevant kernel parameters are named consistently across different systems; Table 17-1 gives an overview. The methods to set them, however, vary. Suggestions for some
platforms are given below. Be warned that it is often necessary to reboot your machine, and possibly even recompile the kernel, to change these settings.

Table 17-1. System V IPC parameters

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
<th>Reasonable values</th>

</tbody>
</table>

The most important shared memory parameter is SHMMAX, the maximum size, in bytes, of a shared memory segment. If you get an error message from `shmget` like Invalid argument, it is likely that this limit has been exceeded. The size of the required shared memory segment varies depending on several PostgreSQL configuration parameters, as shown in Table 17-2. (Any error message you might get will include the exact size of the failed allocation request.) You can, as a temporary solution, lower some of those settings to avoid the failure. While it is possible to get PostgreSQL to run with SHMMAX as small as 2 MB, you need considerably more for acceptable performance. Desirable settings are in the tens to hundreds of megabytes.

Some systems also have a limit on the total amount of shared memory in the system (SHMALL). Make sure this is large enough for PostgreSQL plus any other applications that are using shared memory segments. (Caution: SHMALL is measured in pages rather than bytes on many systems.)

Less likely to cause problems is the minimum size for shared memory segments (SHMMIN), which should be at most approximately 500 kB for PostgreSQL (it is usually just 1). The maximum number of segments system-wide (SHMMNI) or per-process (SHMSEG) are unlikely to cause a problem unless your system has them set to zero.

PostgreSQL uses one semaphore per allowed connection (max_connections) and allowed autovac-
uum worker process (autovacuum_max_workers), in sets of 16. Each such set will also contain a 17th semaphore which contains a “magic number”, to detect collision with semaphore sets used by other applications. The maximum number of semaphores in the system is set by SEMMNS, which consequently must be at least as high as max_connections plus autovacuum_max_workers, plus one extra for each 16 allowed connections plus workers (see the formula in Table 17-1). The parameter SEMMNI determines the limit on the number of semaphore sets that can exist on the system at one time. Hence this parameter must be at least \(\lceil(\text{max_connections} + \text{autovacuum_max_workers}) / 16\rceil\). Lowering the number of allowed connections is a temporary workaround for failures, which are usually confusingly worded No space left on device, from the function semget.

In some cases it might also be necessary to increase SEMMAP to be at least on the order of SEMMNS. This parameter defines the size of the semaphore resource map, in which each contiguous block of available semaphores needs an entry. When a semaphore set is freed it is either added to an existing entry that is adjacent to the freed block or it is registered under a new map entry. If the map is full, the freed semaphores get lost (until reboot). Fragmentation of the semaphore space could over time lead to fewer available semaphores than there should be.

The SEMMSL parameter, which determines how many semaphores can be in a set, must be at least 17 for PostgreSQL.

Various other settings related to “semaphore undo”, such as SEMMNU and SEMUME, are not of concern for PostgreSQL.

AIX

At least as of version 5.1, it should not be necessary to do any special configuration for such parameters as SHMMAX, as it appears this is configured to allow all memory to be used as shared memory. That is the sort of configuration commonly used for other databases such as DB/2.

It might, however, be necessary to modify the global ulimit information in /etc/security/limits, as the default hard limits for file sizes (fsize) and numbers of files (nofiles) might be too low.

BSD/OS

Shared Memory. By default, only 4 MB of shared memory is supported. Keep in mind that shared memory is not pageable; it is locked in RAM. To increase the amount of shared memory supported by your system, add something like the following to your kernel configuration file:

```bash
options "SHMALL=8192"
options "SHMMAX=\(\text{SHMALL} \times \text{PAGE_SIZE}\)"
```

SHMALL is measured in 4 kB pages, so a value of 1024 represents 4 MB of shared memory. Therefore the above increases the maximum shared memory area to 32 MB. For those running 4.3 or later, you will probably also need to increase KERNEL_VIRTUAL_MB above the default 248. Once all changes have been made, recompile the kernel, and reboot.

For those running 4.0 and earlier releases, use bpatch to find the sysptsize value in the current kernel. This is computed dynamically at boot time.

```bash
$ bpatch -r sysptsize
0x9 = 9
```

Next, add SYSPTSIZE as a hard-coded value in the kernel configuration file. Increase the value you found using bpatch. Add 1 for every additional 4 MB of shared memory you desire.

```bash
options "SYSPTSIZE=16"
sysptsize cannot be changed by sysctl.
```

Semaphores. You will probably want to increase the number of semaphores as well; the default system total of 60 will only allow about 50 PostgreSQL connections. Set the values you want in your kernel configuration file, e.g.:
options "SEMMNI=40"
options "SEMMNS=240"

FreeBSD

The default settings are only suitable for small installations (for example, default SHMMAX is 32 MB). Changes can be made via the sysctl or loader interfaces. The following parameters can be set using sysctl:

$$
\text{sysctl -w kern.ipc.shmall=32768} \\
\text{sysctl -w kern.ipc.shmmax=134217728} \\
\text{sysctl -w kern.ipc.semmap=256}
$$

To have these settings persist over reboots, modify /etc/sysctl.conf.

The remaining semaphore settings are read-only as far as sysctl is concerned, but can be changed before boot using the loader prompt:

(loader) \text{set kern.ipc.semmni=256}
(loader) \text{set kern.ipc.semmns=512}
(loader) \text{set kern.ipc.semmnu=256}

Similarly these can be saved between reboots in /boot/loader.conf.

You might also want to configure your kernel to lock shared memory into RAM and prevent it from being paged out to swap. This can be accomplished using the sysctl setting kern.ipc.shm_use_phys.

If running in FreeBSD jails by enabling sysctl’s security.jail.sysvipc_allowed, postmasters running in different jails should be run by different operating system users. This improves security because it prevents non-root users from interfering with shared memory or semaphores in a different jail, and it allows the PostgreSQL IPC cleanup code to function properly. (In FreeBSD 6.0 and later the IPC cleanup code doesn’t properly detect processes in other jails, preventing the running of postmasters on the same port in different jails.)

FreeBSD versions before 4.0 work like OpenBSD (see below).

NetBSD

In NetBSD 5.0 and later, IPC parameters can be adjusted using sysctl, for example:

$$
\text{sysctl -w kern.ipc.shmmax=16777216}
$$

To have these settings persist over reboots, modify /etc/sysctl.conf.

You might also want to configure your kernel to lock shared memory into RAM and prevent it from being paged out to swap. This can be accomplished using the sysctl setting kern.ipc.shm_use_phys.

NetBSD versions before 5.0 work like OpenBSD (see below), except that parameters should be set with the keyword options not option.

OpenBSD

The options SYSVSHM and SYSVSEM need to be enabled when the kernel is compiled. (They are by default.) The maximum size of shared memory is determined by the option SHMMAXPGS (in pages). The following shows an example of how to set the various parameters:

```
option SYSVSHM
option SHMMAXPGS=4096
option SHMSEG=256

option SYSVSEM
option SEMMNI=256
option SEMMNS=512
option SEMMNU=256
```
option SEMMAP=256

You might also want to configure your kernel to lock shared memory into RAM and prevent it from beingpaged out to swap. This can be accomplished using the sysctl setting kern.ipc.shm_use_phys.

HP-UX

The default settings tend to suffice for normal installations. On HP-UX 10, the factory default for SEMMNS is 128, which might be too low for larger database sites.

IPC parameters can be set in the System Administration Manager (SAM) under Kernel Configuration → Configurable Parameters. Hit Create A New Kernel when you’re done.

Linux

The default maximum segment size is 32 MB, which is only adequate for small PostgreSQL installations. However, the remaining defaults are quite generously sized, and usually do not require changes. The maximum shared memory segment size can be changed via the sysctl interface. For example, to allow 128 MB, and explicitly set the maximum total shared memory size to 2097152 pages (the default):

```
$ sysctl -w kernel.shmmax=134217728
$ sysctl -w kernel.shmall=2097152
```

In addition these settings can be saved between reboots in /etc/sysctl.conf.

Older distributions might not have the sysctl program, but equivalent changes can be made by manipulating the /proc file system:

```
$ echo 134217728 > /proc/sys/kernel/shmmax
$ echo 2097152 > /proc/sys/kernel/shmall
```

MacOS X

In OS X 10.2 and earlier, edit the file /System/Library/StartupItems/SystemTuning/SystemTuning and change the values in the following commands:

```
sysctl -w kern.sysv.shmmax
sysctl -w kern.sysv.shmmin
sysctl -w kern.sysv.shmmni
sysctl -w kern.sysv.shmseg
sysctl -w kern.sysv.shmall
```

In OS X 10.3 and later, these commands have been moved to /etc/rc and must be edited there. Note that /etc/rc is usually overwritten by OS X updates (such as 10.3.6 to 10.3.7) so you should expect to have to redo your editing after each update.

In OS X 10.3.9 and later, instead of editing /etc/rc you can create a file named /etc/sysctl.conf, containing variable assignments such as:

```
kern.sysv.shmmax=4194304
kern.sysv.shmmin=1
kern.sysv.shmmni=32
kern.sysv.shmseg=8
kern.sysv.shmall=1024
```

This method is better than editing /etc/rc because your changes will be preserved across system updates. Note that all five shared-memory parameters must be set in /etc/sysctl.conf, else the values will be ignored.

Beware that recent releases of OS X ignore attempts to set SHMMAX to a value that isn’t an exact multiple of 4096.

SHMALL is measured in 4 kB pages on this platform.
In all OS X versions, you’ll need to reboot to make changes in the shared memory parameters take effect.

SCO OpenServer

In the default configuration, only 512 kB of shared memory per segment is allowed. To increase the setting, first change to the directory /etc/conf/cf.d. To display the current value of SHMMAX, run:

```
./configure -y SHMMAX
```

To set a new value for SHMMAX, run:

```
./configure SHMMAX=value
```

where value is the new value you want to use (in bytes). After setting SHMMAX, rebuild the kernel:

```
./link_unix
```

and reboot.

Solaris

At least in version 2.6, the default maximum size of a shared memory segment is too low for PostgreSQL. The relevant settings can be changed in /etc/system, for example:

```
set shmsys:shminfo_shmmax=0x2000000
set shmsys:shminfo_shmmin=1
set shmsys:shminfo_shmmni=256
set shmsys:shminfo_shmseg=256

set semsys:seminfo_semmap=256
set semsys:seminfo_semmin=512
set semsys:seminfo_semmns=512
set semsys:seminfo_semmsl=32
```

You need to reboot for the changes to take effect.

See also http://sunsite.uakom.sk/sunworldonline/swol-09-1997/swol-09-insidesolaris.html for information on shared memory under Solaris.

UnixWare

On UnixWare 7, the maximum size for shared memory segments is only 512 kB in the default configuration. To display the current value of SHMMAX, run:

```
/etc/conf/bin/idtune -g SHMMAX
```

which displays the current, default, minimum, and maximum values. To set a new value for SHMMAX, run:

```
/etc/conf/bin/idtune SHMMAX value
```

where value is the new value you want to use (in bytes). After setting SHMMAX, rebuild the kernel:

```
/etc/conf/bin/idbuild -B
```

and reboot.

### 17.4.2. Resource Limits

Unix-like operating systems enforce various kinds of resource limits that might interfere with the operation of your PostgreSQL server. Of particular importance are limits on the number of processes per user, the number of open files per process, and the amount of memory available to each process. Each of these have a “hard” and a “soft” limit. The soft limit is what actually counts but it can be changed by the user up to the hard limit. The hard limit can only be changed by the root user. The system call `setrlimit` is responsible for setting these parameters. The shell’s built-in command `ulimit` (Bourne shells) or `limit` (csh) is used to control the resource limits from the command line. On BSD-derived systems the file `/etc/login.conf` controls the various resource limits set during login. See the operating system documentation for details. The relevant parameters are `maxproc`, `openfiles`, and `datasize`. For example:

```plaintext
default:\  ...
  :datasize-cur=256M:\
  :maxproc-cur=256:\
  :openfiles-cur=256:\
  ...  
```

(\-cur is the soft limit. Append \-max to set the hard limit.)

Kernels can also have system-wide limits on some resources.

- On Linux `/proc/sys/fs/file-max` determines the maximum number of open files that the kernel will support. It can be changed by writing a different number into the file or by adding an assignment in `/etc/sysctl.conf`. The maximum limit of files per process is fixed at the time the kernel is compiled; see `/usr/src/linux/Documentation/proc.txt` for more information.

The PostgreSQL server uses one process per connection so you should provide for at least as many processes as allowed connections, in addition to what you need for the rest of your system. This is usually not a problem but if you run several servers on one machine things might get tight.

The factory default limit on open files is often set to “socially friendly” values that allow many users to coexist on a machine without using an inappropriate fraction of the system resources. If you run many servers on a machine this is perhaps what you want, but on dedicated servers you might want to raise this limit.

On the other side of the coin, some systems allow individual processes to open large numbers of files; if more than a few processes do so then the system-wide limit can easily be exceeded. If you find this happening, and you do not want to alter the system-wide limit, you can set PostgreSQL’s `max_files_per_process` configuration parameter to limit the consumption of open files.
17.4.3. Linux Memory Overcommit

In Linux 2.4 and later, the default virtual memory behavior is not optimal for PostgreSQL. Because of the way that the kernel implements memory overcommit, the kernel might terminate the PostgreSQL server (the master server process) if the memory demands of another process cause the system to run out of virtual memory.

If this happens, you will see a kernel message that looks like this (consult your system documentation and configuration on where to look for such a message):

Out of Memory: Killed process 12345 (postgres).

This indicates that the postgres process has been terminated due to memory pressure. Although existing database connections will continue to function normally, no new connections will be accepted. To recover, PostgreSQL will need to be restarted.

One way to avoid this problem is to run PostgreSQL on a machine where you can be sure that other processes will not run the machine out of memory. If memory is tight, increasing the swap space of the operating system can help avoiding the problem, because the out-of-memory (OOM) killer is invoked whenever physical memory and swap space are exhausted.

On Linux 2.6 and later, an additional measure is to modify the kernel’s behavior so that it will not “overcommit” memory. Although this setting will not prevent the OOM killer from being invoked altogether, it will lower the chances significantly and will therefore lead to more robust system behavior. This is done by selecting strict overcommit mode via `sysctl`:

```bash
sysctl -w vm.overcommit_memory=2
```

or placing an equivalent entry in `/etc/sysctl.conf`. You might also wish to modify the related setting `vm.overcommit_ratio`. For details see the kernel documentation file `Documentation/vm/overcommit-accounting`.

Some vendors’ Linux 2.4 kernels are reported to have early versions of the 2.6 overcommit `sysctl` parameter. However, setting `vm.overcommit_memory` to 2 on a kernel that does not have the relevant code will make things worse not better. It is recommended that you inspect the actual kernel source code (see the function `vm_enough_memory` in the file `mm/mmap.c`) to verify what is supported in your copy before you try this in a 2.4 installation. The presence of the `overcommit-accounting` documentation file should not be taken as evidence that the feature is there. If in any doubt, consult a kernel expert or your kernel vendor.

17.5. Shutting Down the Server

There are several ways to shut down the database server. You control the type of shutdown by sending different signals to the master `postgres` process.

SIGTERM

After receiving SIGTERM, the server disallows new connections, but lets existing sessions end their work normally. It shuts down only after all of the sessions terminate normally. This is the Smart Shutdown.

1. http://lwn.net/Articles/104179/
Chapter 17. Operating System Environment

SIGINT

The server disallows new connections and sends all existing server processes SIGTERM, which will cause them to abort their current transactions and exit promptly. It then waits for the server processes to exit and finally shuts down. This is the Fast Shutdown.

SIGQUIT

This is the Immediate Shutdown, which will cause the master `postgres` process to send a SIGQUIT to all child processes and exit immediately, without properly shutting itself down. The child processes likewise exit immediately upon receiving SIGQUIT. This will lead to recovery (by replaying the WAL log) upon next start-up. This is recommended only in emergencies.

The `pg_ctl` program provides a convenient interface for sending these signals to shut down the server. Alternatively, you can send the signal directly using `kill` on non-Windows systems. The PID of the `postgres` process can be found using the `ps` program, or from the file `postmaster.pid` in the data directory. For example, to do a fast shutdown:

```
$ kill -INT `head -1 /usr/local/pgsql/data/postmaster.pid`
```

**Important:** It is best not to use SIGKILL to shut down the server. Doing so will prevent the server from releasing shared memory and semaphores, which might then have to be done manually before a new server can be started. Furthermore, SIGKILL kills the `postgres` process without letting it relay the signal to its subprocesses, so it will be necessary to kill the individual subprocesses by hand as well.

17.6. Preventing Server Spoofing

While the server is running, it is not possible for a malicious user to interfere with client/server communications. However, when the server is down it is possible for a local user to spoof the normal server by starting their own server. The spoof server could read passwords and queries sent by clients, but could not return any data because the `PGDATA` directory would still be secure because of directory permissions. Spoofing is possible because any user can start a database server; a client cannot identify an invalid server unless it is specially configured.

The simplest way to prevent invalid servers for local connections is to use a Unix domain socket directory (`unix_socket_directory`) that has write permission only for a trusted local user. This prevents a malicious user from creating their own socket file in that directory. If you are concerned that some applications might still reference `/tmp` for the socket file and hence be vulnerable to spoofing, during operating system startup create symbolic link `/tmp/.s.PGSQL.5432` that points to the relocated socket file. You also might need to modify your `/tmp` cleanup script to preserve the symbolic link.

For TCP connections the server must accept only `hostssl` connections (Section 21.1) and have SSL `server.key` (key) and `server.crt` (certificate) files (Section 17.8). The TCP client must connect using `sslmode='require'` (Section 30.1) and have a `~/.postgresql/root.crt` SSL certificate (Section 30.16).
Chapter 17. Operating System Environment

17.7. Encryption Options

PostgreSQL offers encryption at several levels, and provides flexibility in protecting data from disclosure due to database server theft, unscrupulous administrators, and insecure networks. Encryption might also be required to secure sensitive data such as medical records or financial transactions.

Password Storage Encryption

By default, database user passwords are stored as MD5 hashes, so the administrator cannot determine the actual password assigned to the user. If MD5 encryption is used for client authentication, the unencrypted password is never even temporarily present on the server because the client MD5 encrypts it before being sent across the network.

Encryption For Specific Columns

The contrib function library pgcrypto allows certain fields to be stored encrypted. This is useful if only some of the data is sensitive. The client supplies the decryption key and the data is decrypted on the server and then sent to the client.

The decrypted data and the decryption key are present on the server for a brief time while it is being decrypted and communicated between the client and server. This presents a brief moment where the data and keys can be intercepted by someone with complete access to the database server, such as the system administrator.

Data Partition Encryption

On Linux, encryption can be layered on top of a file system mount using a “loopback device”. This allows an entire file system partition be encrypted on disk, and decrypted by the operating system. On FreeBSD, the equivalent facility is called GEOM Based Disk Encryption, or gbde.

This mechanism prevents unencrypted data from being read from the drives if the drives or the entire computer is stolen. This does not protect against attacks while the file system is mounted, because when mounted, the operating system provides an unencrypted view of the data. However, to mount the file system, you need some way for the encryption key to be passed to the operating system, and sometimes the key is stored somewhere on the host that mounts the disk.

Encrypting Passwords Across A Network

The MD5 authentication method double-encrypts the password on the client before sending it to the server. It first MD5 encrypts it based on the user name, and then encrypts it based on a random salt sent by the server when the database connection was made. It is this double-encrypted value that is sent over the network to the server. Double-encryption not only prevents the password from being discovered, it also prevents another connection from using the same encrypted password to connect to the database server at a later time.

Encrypting Data Across A Network

SSL connections encrypt all data sent across the network: the password, the queries, and the data returned. The pg_hba.conf file allows administrators to specify which hosts can use non-encrypted connections (host) and which require SSL-encrypted connections (hostssl). Also, clients can specify that they connect to servers only via SSL. Stunnel or SSH can also be used to encrypt transmissions.

SSL Host Authentication

It is possible for both the client and server to provide SSL keys or certificates to each other. It takes some extra configuration on each side, but this provides stronger verification of identity than the mere use of passwords. It prevents a computer from pretending to be the server just long enough to read the password send by the client. It also helps prevent “man in the middle” attacks...
where a computer between the client and server pretends to be the server and reads and passes all data between the client and server.

Client-Side Encryption

If the system administrator cannot be trusted, it is necessary for the client to encrypt the data; this way, unencrypted data never appears on the database server. Data is encrypted on the client before being sent to the server, and database results have to be decrypted on the client before being used.

**17.8. Secure TCP/IP Connections with SSL**

PostgreSQL has native support for using SSL connections to encrypt client/server communications for increased security. This requires that OpenSSL is installed on both client and server systems and that support in PostgreSQL is enabled at build time (see Chapter 15).

With SSL support compiled in, the PostgreSQL server can be started with SSL enabled by setting the parameter `ssl` to `on` in `postgresql.conf`. The server will listen for both standard and SSL connections on the same TCP port, and will negotiate with any connecting client on whether to use SSL. By default, this is at the client’s option; see Section 21.1 about how to set up the server to require use of SSL for some or all connections.

PostgreSQL reads the system-wide OpenSSL configuration file. By default, this file is named `openssl.cnf` and is located in the directory reported by `openssl version -d`. This default can be overridden by setting environment variable `OPENSSL_CONF` to the name of the desired configuration file.

OpenSSL supports a wide range of ciphers and authentication algorithms, of varying strength. While a list of ciphers can be specified in the OpenSSL configuration file, you can specify ciphers specifically for use by the database server by modifying `ssl_ciphers` in `postgresql.conf`.

**Note:** It is possible to have authentication without encryption overhead by using `NULL-SHA` or `NULL-MD5` ciphers. However, a man-in-the-middle could read and pass communications between client and server. Also, encryption overhead is minimal compared to the overhead of authentication. For these reasons NULL ciphers are not recommended.

To start in SSL mode, the files `server.crt` and `server.key` must exist in the server’s data directory. These files should contain the server certificate and private key, respectively. If the private key is protected with a passphrase, the server will prompt for the passphrase and will not start until it has been entered.

To require the client to supply a trusted certificate, place certificates of the certificate authorities (CA) you trust in the file `root.crt` in the data directory. A certificate will then be requested from the client during SSL connection startup. (See Section 30.16 for a description of how to set up client certificates.) The server will verify that the client’s certificate is signed by one of the trusted certificate authorities. Certificate Revocation List (CRL) entries are also checked if the file `root.crl` exists. (See http://h71000.www7.hp.com/DOC/83final/BA554_90007/ch04s02.html for diagrams showing SSL certificate usage.)

If the `root.crt` file is not present, client certificates will not be requested or checked. In this mode, SSL provides encrypted communication but not authentication.

The files `server.key`, `server.crt`, `root.crt`, and `root.crl` are only examined during server start; so you must restart the server for changes in them to take effect.
Table 17-3. SSL Server File Usage

<td>client certificate must not be on this list</td>
</tr>
</tbody>
</table>

17.8.1. Creating a Self-Signed Certificate

To create a quick self-signed certificate for the server, use the following OpenSSL command:

openssl req -new -text -out server.req

Fill out the information that openssl asks for. Make sure you enter the local host name as “Common Name”; the challenge password can be left blank. The program will generate a key that is passphrase protected; it will not accept a passphrase that is less than four characters long. To remove the passphrase (as you must if you want automatic start-up of the server), run the commands:

openssl rsa -in privkey.pem -out server.key
rm privkey.pem

Enter the old passphrase to unlock the existing key. Now do:

openssl req -x509 -in server.req -text -key server.key -out server.crt
chmod og-rwx server.key

to turn the certificate into a self-signed certificate and to copy the key and certificate to where the server will look for them. For more details on how to create your server private key and certificate, refer to the OpenSSL documentation.

A self-signed certificate can be used for testing, but a certificate signed by a certificate authority (CA) (either one of the global CAs or a local one) should be used in production so the client can verify the server’s identity.

17.9. Secure TCP/IP Connections with SSH Tunnels

One can use SSH to encrypt the network connection between clients and a PostgreSQL server. Done properly, this provides an adequately secure network connection, even for non-SSL-capable clients.

First make sure that an SSH server is running properly on the same machine as the PostgreSQL server and that you can log in using `ssh` as some user. Then you can establish a secure tunnel with a command like this from the client machine:

```
ssh -L 3333:foo.com:5432 joe@foo.com
```
The first number in the `-L` argument, 3333, is the port number of your end of the tunnel; it can be chosen freely. The second number, 5432, is the remote end of the tunnel: the port number your server is using. The name or IP address between the port numbers is the host with the database server you are going to connect to. In order to connect to the database server using this tunnel, you connect to port 3333 on the local machine:

```
psql -h localhost -p 3333 postgres
```

To the database server it will then look as though you are really user joe@foo.com and it will use whatever authentication procedure was configured for connections from this user and host. Note that the server will not think the connection is SSL-encrypted, since in fact it is not encrypted between the SSH server and the PostgreSQL server. This should not pose any extra security risk as long as they are on the same machine.

In order for the tunnel setup to succeed you must be allowed to connect via `ssh` as joe@foo.com, just as if you had attempted to use `ssh` to set up a terminal session.

**Tip:** Several other applications exist that can provide secure tunnels using a procedure similar in concept to the one just described.
Chapter 18. Server Configuration

There are many configuration parameters that affect the behavior of the database system. In the first section of this chapter, we describe how to set configuration parameters. The subsequent sections discuss each parameter in detail.

18.1. Setting Parameters

All parameter names are case-insensitive. Every parameter takes a value of one of four types: Boolean, integer, floating point, or string. Boolean values can be written as ON, OFF, TRUE, FALSE, YES, NO, 1, 0 (all case-insensitive) or any unambiguous prefix of these.

Some settings specify a memory or time value. Each of these has an implicit unit, which is either kilobytes, blocks (typically eight kilobytes), milliseconds, seconds, or minutes. Default units can be queried by referencing pg_settings.unit. For convenience, a different unit can also be specified explicitly. Valid memory units are kB (kilobytes), MB (megabytes), and GB (gigabytes); valid time units are ms (milliseconds), s (seconds), min (minutes), h (hours), and d (days). Note that the multiplier for memory units is 1024, not 1000.

One way to set these parameters is to edit the file postgresql.conf, which is normally kept in the data directory. (initdb installs a default copy there.) An example of what this file might look like is:

```plaintext
# This is a comment
log_connections = yes
log_destination = 'syslog'
search_path = '$user', public'
shared_buffers = 128MB
```

One parameter is specified per line. The equal sign between name and value is optional. Whitespace is insignificant and blank lines are ignored. Hash marks (#) introduce comments anywhere. Parameter values that are not simple identifiers or numbers must be single-quoted. To embed a single quote in a parameter value, write either two quotes (preferred) or backslash-quote.

In addition to parameter settings, the postgresql.conf file can contain include directives, which specify another file to read and process as if it were inserted into the configuration file at this point. Include directives simply look like:

```plaintext
include 'filename'
```

If the file name is not an absolute path, it is taken as relative to the directory containing the referencing configuration file. Inclusions can be nested.

The configuration file is reread whenever the main server process receives a SIGHUP signal (which is most easily sent by means of pg_ctl reload). The main server process also propagates this signal to all currently running server processes so that existing sessions also get the new value. Alternatively, you can send the signal to a single server process directly. Some parameters can only be set at server start; any changes to their entries in the configuration file will be ignored until the server is restarted.

A second way to set these configuration parameters is to give them as a command-line option to the postgres command, such as:

```plaintext
postgres -c log_connections=yes -c log_destination='syslog'
```
Chapter 18. Server Configuration

Command-line options override any conflicting settings in `postgresql.conf`. Note that this means you won’t be able to change the value on-the-fly by editing `postgresql.conf`, so while the command-line method might be convenient, it can cost you flexibility later.

Occasionally it is useful to give a command line option to one particular session only. The environment variable `PGOPTIONS` can be used for this purpose on the client side:

```bash
eval PGOPTIONS=''-c geqo=off'' psql
```

(This works for any `libpq`-based client application, not just `psql`.) Note that this won’t work for parameters that are fixed when the server is started or that must be specified in `postgresql.conf`.

Furthermore, it is possible to assign a set of parameter settings to a user or a database. Whenever a session is started, the default settings for the user and database involved are loaded. The commands `ALTER USER` and `ALTER DATABASE`, respectively, are used to configure these settings. Per-database settings override anything received from the `postgres` command-line or the configuration file, and in turn are overridden by per-user settings; both are overridden by per-session settings.

Some parameters can be changed in individual SQL sessions with the `SET` command, for example:

```sql
SET ENABLE_SEQSCAN TO OFF;
```

If `SET` is allowed, it overrides all other sources of values for the parameter. Some parameters cannot be changed via `SET`: for example, if they control behavior that cannot be changed without restarting the entire PostgreSQL server. Also, some parameters can be modified via `SET` or `ALTER` by superusers, but not by ordinary users.

The `SHOW` command allows inspection of the current values of all parameters.

The virtual table `pg_settings` (described in Section 44.51) also allows displaying and updating session run-time parameters. It is equivalent to `SHOW` and `SET`, but can be more convenient to use because it can be joined with other tables, or selected from using any desired selection condition.

18.2. File Locations

In addition to the `postgresql.conf` file already mentioned, PostgreSQL uses two other manually-edited configuration files, which control client authentication (their use is discussed in Chapter 21). By default, all three configuration files are stored in the database cluster’s data directory. The parameters described in this section allow the configuration files to be placed elsewhere. (Doing so can ease administration. In particular it is often easier to ensure that the configuration files are properly backed-up when they are kept separate.)

`data_directory` (string)

Specifies the directory to use for data storage. This parameter can only be set at server start.

`config_file` (string)

Specifies the main server configuration file (customarily called `postgresql.conf`). This parameter can only be set on the `postgres` command line.

`hba_file` (string)

Specifies the configuration file for host-based authentication (customarily called `pg_hba.conf`). This parameter can only be set at server start.
ident_file(string)

Specifies the configuration file for ident authentication (customarily called pg_ident.conf). This parameter can only be set at server start.

external_pid_file(string)

Specifies the name of an additional process-id (PID) file that the server should create for use by server administration programs. This parameter can only be set at server start.

In a default installation, none of the above parameters are set explicitly. Instead, the data directory is specified by the -D command-line option or the PGDATA environment variable, and the configuration files are all found within the data directory.

If you wish to keep the configuration files elsewhere than the data directory, the postgres -D command-line option or PGDATA environment variable must point to the directory containing the configuration files, and the data_directory parameter must be set in postgresql.conf (or on the command line) to show where the data directory is actually located. Notice that data_directory overrides -D and PGDATA for the location of the data directory, but not for the location of the configuration files.

If you wish, you can specify the configuration file names and locations individually using the parameters config_file, hba_file and/or ident_file. config_file can only be specified on the postgres command line, but the others can be set within the main configuration file. If all three parameters plus data_directory are explicitly set, then it is not necessary to specify -D or PGDATA.

When setting any of these parameters, a relative path will be interpreted with respect to the directory in which postgres is started.

Chapter 18. Server Configuration

18.3. Connections and Authentication

18.3.1. Connection Settings

listen_addresses(string)

Specifies the TCP/IP address(es) on which the server is to listen for connections from client applications. The value takes the form of a comma-separated list of host names and/or numeric IP addresses. The special entry * corresponds to all available IP interfaces. If the list is empty, the server does not listen on any IP interface at all, in which case only Unix-domain sockets can be used to connect to it. The default value is localhost, which allows only local “loopback” connections to be made. This parameter can only be set at server start.

port(integer)

The TCP port the server listens on; 5432 by default. Note that the same port number is used for all IP addresses the server listens on. This parameter can only be set at server start.

max_connections(integer)

Determines the maximum number of concurrent connections to the database server. The default is typically 100 connections, but might be less if your kernel settings will not support it (as determined during initdb). This parameter can only be set at server start.

Increasing this parameter might cause PostgreSQL to request more System V shared memory or semaphores than your operating system’s default configuration allows. See Section 17.4.1 for information on how to adjust those parameters, if necessary.
superuser_reserved_connections (integer)

Determines the number of connection “slots” that are reserved for connections by PostgreSQL superusers. At most max_connections connections can ever be active simultaneously. Whenever the number of active concurrent connections is at least max_connections minus superuser_reserved_connections, new connections will be accepted only for superusers.

The default value is three connections. The value must be less than the value of max_connections. This parameter can only be set at server start.

unix_socket_directory (string)

Specifies the directory of the Unix-domain socket on which the server is to listen for connections from client applications. The default is normally /tmp, but can be changed at build time. This parameter can only be set at server start.

unix_socket_group (string)

Sets the owning group of the Unix-domain socket. (The owning user of the socket is always the user that starts the server.) In combination with the parameter unix_socket_permissions this can be used as an additional access control mechanism for Unix-domain connections. By default this is the empty string, which selects the default group for the current user. This parameter can only be set at server start.

unix_socket_permissions (integer)

Sets the access permissions of the Unix-domain socket. Unix-domain sockets use the usual Unix file system permission set. The parameter value is expected to be a numeric mode specification in the form accepted by the chmod and umask system calls. (To use the customary octal format the number must start with a 0 (zero).)

The default permissions are 0777, meaning anyone can connect. Reasonable alternatives are 0770 (only user and group, see also unix_socket_group) and 0700 (only user). (Note that for a Unix-domain socket, only write permission matters and so there is no point in setting or revoking read or execute permissions.)

This access control mechanism is independent of the one described in Chapter 21.

This parameter can only be set at server start.

bonjour_name (string)

Specifies the Bonjour broadcast name. The computer name is used if this parameter is set to the empty string “” (which is the default). This parameter is ignored if the server was not compiled with Bonjour support. This parameter can only be set at server start.

tcp_keepalives_idle (integer)

On systems that support the TCP_KEEPIDLE socket option, specifies the number of seconds between sending keepalives on an otherwise idle connection. A value of zero uses the system default. If TCP_KEEPIDLE is not supported, this parameter must be zero. This parameter is ignored for connections made via a Unix-domain socket.

tcp_keepalives_interval (integer)

On systems that support the TCP_KEEPINTVL socket option, specifies how long, in seconds, to wait for a response to a keepalive before retransmitting. A value of zero uses the system default. If TCP_KEEPINTVL is not supported, this parameter must be zero. This parameter is ignored for connections made via a Unix-domain socket.
tcp_keepalives_count (integer)

On systems that support the TCP_KEEPCNT socket option, specifies how many keepalives can be lost before the connection is considered dead. A value of zero uses the system default. If TCP_KEEPCNT is not supported, this parameter must be zero. This parameter is ignored for connections made via a Unix-domain socket.

18.3.2. Security and Authentication

authentication_timeout (integer)

Maximum time to complete client authentication, in seconds. If a would-be client has not completed the authentication protocol in this much time, the server breaks the connection. This prevents hung clients from occupying a connection indefinitely. The default is one minute (1m). This parameter can only be set in the postgresql.conf file or on the server command line.

ssl (boolean)

Enables SSL connections. Please read Section 17.8 before using this. The default is off. This parameter can only be set at server start.

ssl_renegotiation_limit (integer)

Specifies how much data can flow over an SSL encrypted connection before renegotiation of the session will take place. Renegotiation of the session decreases the chance of doing cryptanalysis when large amounts of data are sent, but it also carries a large performance penalty. The sum of sent and received traffic is used to check the limit. If the parameter is set to 0, renegotiation is disabled. The default is 512MB.

Note: SSL libraries from before November 2009 are insecure when using SSL renegotiation, due to a vulnerability in the SSL protocol. As a stop-gap fix for this vulnerability, some vendors also shipped SSL libraries incapable of doing renegotiation. If any of these libraries are in use on the client or server, SSL renegotiation should be disabled.

ssl_ciphers (string)

Specifies a list of SSL ciphers that are allowed to be used on secure connections. See the openssl manual page for a list of supported ciphers. This parameter is unavailable unless the server is compiled with support for SSL.

password_encryption (boolean)

When a password is specified in CREATE USER or ALTER USER without writing either ENCRYPTED or UNENCRYPTED, this parameter determines whether the password is to be encrypted. The default is on (encrypt the password).

krb_realm (string)

Sets the realm to match Kerberos, GSSAPI and SSPI user names against. See Section 21.2.5, Section 21.2.3 or Section 21.2.4 for details. This parameter can only be set at server start.

krb_server_keyfile (string)

Sets the location of the Kerberos server key file. See Section 21.2.5 or Section 21.2.3 for details. This parameter can only be set at server start.
krb_srvname (string)

Sets the Kerberos service name. See Section 21.2.5 for details. This parameter can only be set at server start.

krb_server_hostname (string)

Sets the host name part of the service principal. This, combined with krb_srvname, is used to generate the complete service principal, that is krb_srvname/krb_server_hostname@REALM. If not set, the default is the server hostname. See Section 21.2.5 for details. This parameter can only be set at server start.

krb_caseins_users (boolean)

Sets whether Kerberos and GSSAPI user names should be treated case-insensitively. The default is off (case sensitive). This parameter can only be set at server start.

db_user_namespace (boolean)

This parameter enables per-database user names. It is off by default. This parameter can only be set in the postgresql.conf file or on the server command line.

If this is on, you should create users as username@dbname. When username is passed by a connecting client, @ and the database name are appended to the user name and that database-specific user name is looked up by the server. Note that when you create users with names containing @ within the SQL environment, you will need to quote the user name.

With this parameter enabled, you can still create ordinary global users. Simply append @ when specifying the user name in the client. The @ will be stripped off before the user name is looked up by the server.

Note: This feature is intended as a temporary measure until a complete solution is found. At that time, this option will be removed.

18.4. Resource Consumption

18.4.1. Memory

shared_buffers (integer)

Sets the amount of memory the database server uses for shared memory buffers. The default is typically 32 megabytes (32MB), but might be less if your kernel settings will not support it (as determined during initdb). This setting must be at least 128 kilobytes and at least 16 kilobytes times max_connections. (Non-default values of BLCKSZ change the minimum.) However, settings significantly higher than the minimum are usually needed for good performance. This parameter can only be set at server start.

If you have a dedicated database server with 1GB or more of RAM, a reasonable starting value for shared_buffers is 25% of the memory in your system. There are some workloads where even large settings for shared_buffers are effective, but because PostgreSQL also relies on the operating system cache, it is unlikely that an allocation of more than 40% of RAM to
shared_buffers will work better than a smaller amount. Larger settings for shared_buffers usually require a corresponding increase in checkpoint_segments, in order to spread out the process of writing large quantities of new or changed data over a longer period of time.

On systems with less than 1GB of RAM, a smaller percentage of RAM is appropriate, so as to leave adequate space for the operating system. Also, on Windows, large values for shared_buffers aren’t as effective. You may find better results keeping the setting relatively low and using the operating system cache more instead. The useful range for shared_buffers on Windows systems is generally from 64MB to 512MB.

Increasing this parameter might cause PostgreSQL to request more System V shared memory than your operating system’s default configuration allows. See Section 17.4.1 for information on how to adjust those parameters, if necessary.

temp_buffers (integer)

Sets the maximum number of temporary buffers used by each database session. These are session-local buffers used only for access to temporary tables. The default is eight megabytes (8MB). The setting can be changed within individual sessions, but only up until the first use of temporary tables within a session; subsequent attempts to change the value will have no effect on that session.

A session will allocate temporary buffers as needed up to the limit given by temp_buffers. The cost of setting a large value in sessions that do not actually need a lot of temporary buffers is only a buffer descriptor, or about 64 bytes, per increment in temp_buffers. However if a buffer is actually used an additional 8192 bytes will be consumed for it (or in general, BLCKSZ bytes).

max_prepared_transactions (integer)

Sets the maximum number of transactions that can be in the “prepared” state simultaneously (see PREPARE TRANSACTION). Setting this parameter to zero disables the prepared-transaction feature. The default is five transactions. This parameter can only be set at server start.

If you are not using prepared transactions, this parameter may as well be set to zero. If you are using them, you will probably want max_prepared_transactions to be at least as large as max_connections, to avoid unwanted failures at the prepare step.

Increasing this parameter might cause PostgreSQL to request more System V shared memory than your operating system’s default configuration allows. See Section 17.4.1 for information on how to adjust those parameters, if necessary.

work_mem (integer)

Specifies the amount of memory to be used by internal sort operations and hash tables before switching to temporary disk files. The value is defaults to one megabyte (1MB). Note that for a complex query, several sort or hash operations might be running in parallel; each one will be allowed to use as much memory as this value specifies before it starts to put data into temporary files. Also, several running sessions could be doing such operations concurrently. So the total memory used could be many times the value of work_mem; it is necessary to keep this fact in mind when choosing the value. Sort operations are used for ORDER BY, DISTINCT, and merge joins. Hash tables are used in hash joins, hash-based aggregation, and hash-based processing of IN subqueries.

maintenance_work_mem (integer)

Specifies the maximum amount of memory to be used in maintenance operations, such as VACUUM, CREATE INDEX, and ALTER TABLE ADD FOREIGN KEY. It defaults to 16 megabytes (16MB). Since only one of these operations can be executed at a time by a database session, and an installation normally doesn’t have many of them running concurrently, it’s safe to set this
value significantly larger than `work_mem`. Larger settings might improve performance for vacuuming and for restoring database dumps.

Note that when autovacuum runs, up to `autovacuum_max_workers` times this memory may be allocated, so be careful not to set the default value too high.

```sql
max_stack_depth (integer)
```

Specifies the maximum safe depth of the server’s execution stack. The ideal setting for this parameter is the actual stack size limit enforced by the kernel (as set by `ulimit -s` or local equivalent), less a safety margin of a megabyte or so. The safety margin is needed because the stack depth is not checked in every routine in the server, but only in key potentially-recursive routines such as expression evaluation. The default setting is two megabytes (2MB), which is conservatively small and unlikely to risk crashes. However, it might be too small to allow execution of complex functions. Only superusers can change this setting.

Setting `max_stack_depth` higher than the actual kernel limit will mean that a runaway recursive function can crash an individual backend process. On platforms where PostgreSQL can determine the kernel limit, it will not let you set this variable to an unsafe value. However, not all platforms provide the information, so caution is recommended in selecting a value.

### 18.4.2. Free Space Map

These parameters control the size of the shared free space map (FSM), which tracks the locations of unused space in the database. An undersized free space map can cause the database to consume increasing amounts of disk space over time, because free space that is not in the map cannot be reused; instead PostgreSQL will request more disk space from the operating system when it needs to store new data. The last few lines displayed by a database-wide `VACUUM VERBOSE` command can help in determining if the current settings are adequate. A `NOTICE` message is also printed during such an operation if the current settings are too low.

Increasing these parameters might cause PostgreSQL to request more System V shared memory than your operating system’s default configuration allows. See Section 17.4.1 for information on how to adjust those parameters, if necessary.

```sql
max_fsm_pages (integer)
```

Sets the maximum number of disk pages for which free space will be tracked in the shared free-space map. Six bytes of shared memory are consumed for each page slot. This setting must be at least 16 * `max_fsm_relations`. The default is chosen by initdb depending on the amount of available memory, and can range from 20k to 200k pages. This parameter can only be set at server start.

```sql
max_fsm_relations (integer)
```

Sets the maximum number of relations (tables and indexes) for which free space will be tracked in the shared free-space map. Roughly seventy bytes of shared memory are consumed for each slot. The default is one thousand relations. This parameter can only be set at server start.

**Note:** See the `VACUUM` command for information on setting this parameter.
18.4.3. Kernel Resource Usage

**max_files_per_process (integer)**

Sets the maximum number of simultaneously open files allowed to each server subprocess. The default is one thousand files. If the kernel is enforcing a safe per-process limit, you don’t need to worry about this setting. But on some platforms (notably, most BSD systems), the kernel will allow individual processes to open many more files than the system can really support when a large number of processes all try to open that many files. If you find yourself seeing “Too many open files” failures, try reducing this setting. This parameter can only be set at server start.

**shared_preload_libraries (string)**

This variable specifies one or more shared libraries that are to be preloaded at server start. If more than one library is to be loaded, separate their names with commas. For example, ‘$libdir/mylib’ would cause mylib.so (or on some platforms, mylib.sl) to be preloaded from the installation’s standard library directory. This parameter can only be set at server start.

PostgreSQL procedural language libraries can be preloaded in this way, typically by using the syntax ‘$libdir/plXXX’ where XXX is pgsql, perl, tcl, or python.

By preloading a shared library, the library startup time is avoided when the library is first used. However, the time to start each new server process might increase slightly, even if that process never uses the library. So this parameter is recommended only for libraries that will be used in most sessions.

**Note:** On Windows hosts, preloading a library at server start will not reduce the time required to start each new server process; each server process will re-load all preload libraries. However, shared_preload_libraries is still useful on Windows hosts because some shared libraries may need to perform certain operations that only take place at postmaster start (for example, a shared library may need to reserve lightweight locks or shared memory and you can’t do that after the postmaster has started).

If a specified library is not found, the server will fail to start.

Every PostgreSQL-supported library has a “magic block” that is checked to guarantee compatibility. For this reason, non-PostgreSQL libraries cannot be loaded in this way.

18.4.4. Cost-Based Vacuum Delay

During the execution of `VACUUM` and `ANALYZE` commands, the system maintains an internal counter that keeps track of the estimated cost of the various I/O operations that are performed. When the accumulated cost reaches a limit (specified by `vacuum_cost_limit`), the process performing the operation will sleep for a while (specified by `vacuum_cost_delay`). Then it will reset the counter and continue execution.

The intent of this feature is to allow administrators to reduce the I/O impact of these commands on concurrent database activity. There are many situations in which it is not very important that maintenance commands like `VACUUM` and `ANALYZE` finish quickly; however, it is usually very important that these commands do not significantly interfere with the ability of the system to perform other database operations. Cost-based vacuum delay provides a way for administrators to achieve this.

This feature is disabled by default. To enable it, set the `vacuum_cost_delay` variable to a nonzero value.
vacuum_cost_delay (integer)

The length of time, in milliseconds, that the process will sleep when the cost limit has been exceeded. The default value is zero, which disables the cost-based vacuum delay feature. Positive values enable cost-based vacuuming. Note that on many systems, the effective resolution of sleep delays is 10 milliseconds; setting vacuum_cost_delay to a value that is not a multiple of 10 might have the same results as setting it to the next higher multiple of 10.

vacuum_cost_page_hit (integer)

The estimated cost for vacuuming a buffer found in the shared buffer cache. It represents the cost to lock the buffer pool, lookup the shared hash table and scan the content of the page. The default value is one.

vacuum_cost_page_miss (integer)

The estimated cost for vacuuming a buffer that has to be read from disk. This represents the effort to lock the buffer pool, lookup the shared hash table, read the desired block in from the disk and scan its content. The default value is 10.

vacuum_cost_page_dirty (integer)

The estimated cost charged when vacuum modifies a block that was previously clean. It represents the extra I/O required to flush the dirty block out to disk again. The default value is 20.

vacuum_cost_limit (integer)

The accumulated cost that will cause the vacuuming process to sleep. The default value is 200.

Note: There are certain operations that hold critical locks and should therefore complete as quickly as possible. Cost-based vacuum delays do not occur during such operations. Therefore it is possible that the cost accumulates far higher than the specified limit. To avoid uselessly long delays in such cases, the actual delay is calculated as vacuum_cost_delay * accumulated_balance / vacuum_cost_limit with a maximum of vacuum_cost_delay * 4.

18.4.5. Background Writer

There is a separate server process called the background writer, whose function is to issue writes of “dirty” shared buffers. The intent is that server processes handling user queries should seldom or never have to wait for a write to occur, because the background writer will do it. However there is a net overall increase in I/O load, because a repeatedly-dirtied page might otherwise be written only once per checkpoint interval, but the background writer might write it several times in the same interval. The parameters discussed in this subsection can be used to tune the behavior for local needs.

bgwriter_delay (integer)

Specifies the delay between activity rounds for the background writer. In each round the writer issues writes for some number of dirty buffers (controllable by the following parameters). It then sleeps for bgwriter_delay milliseconds, and repeats. The default value is 200 milliseconds (200ms). Note that on many systems, the effective resolution of sleep delays is 10 milliseconds; setting bgwriter_delay to a value that is not a multiple of 10 might have the same results as setting it to the next higher multiple of 10. This parameter can only be set in the postgresql.conf file or on the server command line.
bgwriter_lru_maxpages (integer)

In each round, no more than this many buffers will be written by the background writer. Setting this to zero disables background writing (except for checkpoint activity). The default value is 100 buffers. This parameter can only be set in the `postgresql.conf` file or on the server command line.

bgwriter_lru_multiplier (floating point)

The number of dirty buffers written in each round is based on the number of new buffers that have been needed by server processes during recent rounds. The average recent need is multiplied by `bgwriter_lru_multiplier` to arrive at an estimate of the number of buffers that will be needed during the next round. Dirty buffers are written until there are that many clean, reusable buffers available. (However, no more than `bgwriter_lru_maxpages` buffers will be written per round.) Thus, a setting of 1.0 represents a “just in time” policy of writing exactly the number of buffers predicted to be needed. Larger values provide some cushion against spikes in demand, while smaller values intentionally leave writes to be done by server processes. The default is 2.0. This parameter can only be set in the `postgresql.conf` file or on the server command line.

Smaller values of `bgwriter_lru_maxpages` and `bgwriter_lru_multiplier` reduce the extra I/O load caused by the background writer, but make it more likely that server processes will have to issue writes for themselves, delaying interactive queries.

18.5. Write Ahead Log

See also Section 28.4 for details on WAL and checkpoint tuning.

18.5.1. Settings

fsync (boolean)

If this parameter is on, the PostgreSQL server will try to make sure that updates are physically written to disk, by issuing `fsync()` system calls or various equivalent methods (see `wal_sync_method`). This ensures that the database cluster can recover to a consistent state after an operating system or hardware crash.

However, using `fsync` results in a performance penalty: when a transaction is committed, PostgreSQL must wait for the operating system to flush the write-ahead log to disk. When `fsync` is disabled, the operating system is allowed to do its best in buffering, ordering, and delaying writes. This can result in significantly improved performance. However, if the system crashes, the results of the last few committed transactions might be lost in part or whole. In the worst case, unrecoverable data corruption might occur. (Crashes of the database software itself are not a risk factor here. Only an operating-system-level crash creates a risk of corruption.)

Due to the risks involved, there is no universally correct setting for `fsync`. Some administrators always disable `fsync`, while others only turn it off during initial bulk data loads, where there is a clear restart point if something goes wrong. Others always leave `fsync` enabled. The default is to enable `fsync`, for maximum reliability. If you trust your operating system, your hardware, and your utility company (or your battery backup), you can consider disabling `fsync`.

In many situations, turning off `synchronous_commit` for noncritical transactions can provide much of the potential performance benefit of turning off `fsync`, without the attendant risks of data corruption.
Chapter 18. Server Configuration

This parameter can only be set in the `postgresql.conf` file or on the server command line. If you turn this parameter off, also consider turning off `full_page_writes`.

```plaintext
synchronous_commit (boolean)
```

Specifies whether transaction commit will wait for WAL records to be written to disk before the command returns a “success” indication to the client. The default, and safe, setting is `on`. When `off`, there can be a delay between when success is reported to the client and when the transaction is really guaranteed to be safe against a server crash. (The maximum delay is three times `wal_writer_delay`.) Unlike `fsync`, setting this parameter to `off` does not create any risk of database inconsistency: a crash might result in some recent allegedly-committed transactions being lost, but the database state will be just the same as if those transactions had been aborted cleanly. So, turning `synchronous_commit` off can be a useful alternative when performance is more important than exact certainty about the durability of a transaction. For more discussion see Section 28.3.

This parameter can be changed at any time; the behavior for any one transaction is determined by the setting in effect when it commits. It is therefore possible, and useful, to have some transactions commit synchronously and others asynchronously. For example, to make a single multi-statement transaction commit asynchronously when the default is the opposite, issue `SET LOCAL synchronous_commit TO OFF` within the transaction.

```plaintext
wal_sync_method (string)
```

Method used for forcing WAL updates out to disk. If `fsync` is off then this setting is irrelevant, since updates will not be forced out at all. Possible values are:

- `open_datasync` (write WAL files with `open()` option `O_DSYNC`)
- `fdatasync` (call `fdatasync()` at each commit)
- `fsync` (call `fsync()` at each commit)
- `fsync_writethrough` (call `fsync()` at each commit, forcing write-through of any disk write cache)
- `open_sync` (write WAL files with `open()` option `O_SYNC`)

The `open_*` options also use `O_DIRECT` if available. Not all of these choices are available on all platforms. The default is the first method in the above list that is supported by the platform, except that `fdatasync` is the default on Linux. The default is not necessarily ideal; it might be necessary to change this setting or other aspects of your system configuration in order to create a crash-safe configuration or achieve optimal performance. These aspects are discussed in Section 28.1. This parameter can only be set in the `postgresql.conf` file or on the server command line.

```plaintext
full_page_writes (boolean)
```

When this parameter is on, the PostgreSQL server writes the entire content of each disk page to WAL during the first modification of that page after a checkpoint. This is needed because a page write that is in process during an operating system crash might be only partially completed, leading to an on-disk page that contains a mix of old and new data. The row-level change data normally stored in WAL will not be enough to completely restore such a page during post-crash recovery. Storing the full page image guarantees that the page can be correctly restored, but at a price in increasing the amount of data that must be written to WAL. (Because WAL replay always starts from a checkpoint, it is sufficient to do this during the first change of each page after a checkpoint. Therefore, one way to reduce the cost of full-page writes is to increase the checkpoint interval parameters.)
Turning this parameter off speeds normal operation, but might lead to a corrupt database after an operating system crash or power failure. The risks are similar to turning off fsync, though smaller. It might be safe to turn off this parameter if you have hardware (such as a battery-backed disk controller) or file-system software that reduces the risk of partial page writes to an acceptably low level (e.g., ReiserFS 4).

Turning off this parameter does not affect use of WAL archiving for point-in-time recovery (PITR) (see Section 24.3).

This parameter can only be set in the postgresql.conf file or on the server command line. The default is on.

### wal_buffers

The amount of memory used in shared memory for WAL data. The default is 64 kilobytes (64kB). The setting need only be large enough to hold the amount of WAL data generated by one typical transaction, since the data is written out to disk at every transaction commit. This parameter can only be set at server start.

Increasing this parameter might cause PostgreSQL to request more System V shared memory than your operating system’s default configuration allows. See Section 17.4.1 for information on how to adjust those parameters, if necessary.

### wal_writer_delay

Specifies the delay between activity rounds for the WAL writer. In each round the writer will flush WAL to disk. It then sleeps for wal_writer_delay milliseconds, and repeats. The default value is 200 milliseconds (200ms). Note that on many systems, the effective resolution of sleep delays is 10 milliseconds; setting wal_writer_delay to a value that is not a multiple of 10 might have the same results as setting it to the next higher multiple of 10. This parameter can only be set in the postgresql.conf file or on the server command line.

### commit_delay

Time delay between writing a commit record to the WAL buffer and flushing the buffer out to disk, in microseconds. A nonzero delay can allow multiple transactions to be committed with only one fsync() system call, if system load is high enough that additional transactions become ready to commit within the given interval. But the delay is just wasted if no other transactions become ready to commit. Therefore, the delay is only performed if at least commit_siblings other transactions are active at the instant that a server process has written its commit record. The default is zero (no delay).

### commit_siblings

Minimum number of concurrent open transactions to require before performing the commit_delay delay. A larger value makes it more probable that at least one other transaction will become ready to commit during the delay interval. The default is five transactions.

### 18.5.2. Checkpoints

### checkpoint_segments

Maximum number of log file segments between automatic WAL checkpoints (each segment is normally 16 megabytes). The default is three segments. Increasing this parameter can increase the amount of time needed for crash recovery. This parameter can only be set in the postgresql.conf file or on the server command line.
checkpoint_timeout (integer)

Maximum time between automatic WAL checkpoints, in seconds. The default is five minutes (5min). Increasing this parameter can increase the amount of time needed for crash recovery. This parameter can only be set in the `postgresql.conf` file or on the server command line.

checkpoint_completion_target (floating point)

Specifies the target length of checkpoints, as a fraction of the checkpoint interval. The default is 0.5. This parameter can only be set in the `postgresql.conf` file or on the server command line.

checkpoint_warning (integer)

Write a message to the server log if checkpoints caused by the filling of checkpoint segment files happen closer together than this many seconds (which suggests that `checkpoint_segments` ought to be raised). The default is 30 seconds (30s). Zero disables the warning. This parameter can only be set in the `postgresql.conf` file or on the server command line.

18.5.3. Archiving

archive_mode (boolean)

When `archive_mode` is enabled, completed WAL segments can be sent to archive storage by setting `archive_command`. `archive_mode` and `archive_command` are separate variables so that `archive_command` can be changed without leaving archiving mode. This parameter can only be set at server start.

archive_command (string)

The shell command to execute to archive a completed segment of the WAL file series. Any %p in the string is replaced by the path name of the file to archive, and any %f is replaced by the file name only. (The path name is relative to the working directory of the server, i.e., the cluster’s data directory.) Use %% to embed an actual % character in the command. For more information see Section 24.3.1. This parameter can only be set in the `postgresql.conf` file or on the server command line. It is ignored unless `archive_mode` was enabled at server start. If `archive_command` is an empty string (the default) while `archive_mode` is enabled, then WAL archiving is temporarily disabled, but the server continues to accumulate WAL segment files in the expectation that a command will soon be provided.

It is important for the command to return a zero exit status if and only if it succeeds. Examples:

```
archive_command = 'cp "%p" /mnt/server/archivedir/"%f"
archive_command = 'copy "%p" "C:\server\archivedir\%f"'  # Windows
```

archive_timeout (integer)

The `archive_command` is only invoked on completed WAL segments. Hence, if your server generates little WAL traffic (or has slack periods where it does so), there could be a long delay between the completion of a transaction and its safe recording in archive storage. To put a limit on how old unarchived data can be, you can set `archive_timeout` to force the server to switch to a new WAL segment file periodically. When this parameter is greater than zero, the server will switch to a new segment file whenever this many seconds have elapsed since the last segment file switch. Note that archived files that are closed early due to a forced switch are still the same length as completely full files. Therefore, it is unwise to use a very short `archive_timeout` — it will bloat your archive storage. `archive_timeout` settings of a minute or so are usually reasonable. This parameter can only be set in the `postgresql.conf` file or on the server command line.
18.6. Query Planning

18.6.1. Planner Method Configuration

These configuration parameters provide a crude method of influencing the query plans chosen by the query optimizer. If the default plan chosen by the optimizer for a particular query is not optimal, a temporary solution can be found by using one of these configuration parameters to force the optimizer to choose a different plan. Turning one of these settings off permanently is seldom a good idea, however. Better ways to improve the quality of the plans chosen by the optimizer include adjusting the Planner Cost Constants, running ANALYZE more frequently, increasing the value of the default_statistics_target configuration parameter, and increasing the amount of statistics collected for specific columns using ALTER TABLE SET STATISTICS.

`enable_bitmapscan (boolean)`
Enables or disables the query planner’s use of bitmap-scan plan types. The default is on.

`enable_hashagg (boolean)`
Enables or disables the query planner’s use of hashed aggregation plan types. The default is on.

`enable_hashjoin (boolean)`
Enables or disables the query planner’s use of hash-join plan types. The default is on.

`enable_indexscan (boolean)`
Enables or disables the query planner’s use of index-scan plan types. The default is on.

`enable_mergejoin (boolean)`
Enables or disables the query planner’s use of merge-join plan types. The default is on.

`enable_nestloop (boolean)`
Enables or disables the query planner’s use of nested-loop join plans. It’s not possible to suppress nested-loop joins entirely, but turning this variable off discourages the planner from using one if there are other methods available. The default is on.

`enable_seqscan (boolean)`
Enables or disables the query planner’s use of sequential scan plan types. It’s not possible to suppress sequential scans entirely, but turning this variable off discourages the planner from using one if there are other methods available. The default is on.

`enable_sort (boolean)`
Enables or disables the query planner’s use of explicit sort steps. It’s not possible to suppress explicit sorts entirely, but turning this variable off discourages the planner from using one if there are other methods available. The default is on.

`enable_tidscan (boolean)`
Enables or disables the query planner’s use of TID scan plan types. The default is on.

18.6.2. Planner Cost Constants

The cost variables described in this section are measured on an arbitrary scale. Only their relative values matter, hence scaling them all up or down by the same factor will result in no change in the planner’s choices. Traditionally, these variables have been referenced to sequential page fetches as the...
unit of cost; that is, `seq_page_cost` is conventionally set to 1.0 and the other cost variables are set with reference to that. But you can use a different scale if you prefer, such as actual execution times in milliseconds on a particular machine.

**Note:** Unfortunately, there is no well-defined method for determining ideal values for the cost variables. They are best treated as averages over the entire mix of queries that a particular installation will get. This means that changing them on the basis of just a few experiments is very risky.

`seq_page_cost` *(floating point)*

Sets the planner’s estimate of the cost of a disk page fetch that is part of a series of sequential fetches. The default is 1.0.

`random_page_cost` *(floating point)*

Sets the planner’s estimate of the cost of a non-sequentially-fetched disk page. The default is 4.0. Reducing this value relative to `seq_page_cost` will cause the system to prefer index scans; raising it will make index scans look relatively more expensive. You can raise or lower both values together to change the importance of disk I/O costs relative to CPU costs, which are described by the following parameters.

**Tip:** Although the system will let you set `random_page_cost` to less than `seq_page_cost`, it is not physically sensible to do so. However, setting them equal makes sense if the database is entirely cached in RAM, since in that case there is no penalty for touching pages out of sequence. Also, in a heavily-cached database you should lower both values relative to the CPU parameters, since the cost of fetching a page already in RAM is much smaller than it would normally be.

`cpu_tuple_cost` *(floating point)*

Sets the planner’s estimate of the cost of processing each row during a query. The default is 0.01.

`cpu_index_tuple_cost` *(floating point)*

Sets the planner’s estimate of the cost of processing each index entry during an index scan. The default is 0.005.

`cpu_operator_cost` *(floating point)*

Sets the planner’s estimate of the cost of processing each operator or function executed during a query. The default is 0.0025.

`effective_cache_size` *(integer)*

Sets the planner’s assumption about the effective size of the disk cache that is available to a single query. This is factored into estimates of the cost of using an index; a higher value makes it more likely index scans will be used, a lower value makes it more likely sequential scans will be used. When setting this parameter you should consider both PostgreSQL’s shared buffers and the portion of the kernel’s disk cache that will be used for PostgreSQL data files. Also, take into account the expected number of concurrent queries on different tables, since they will have to share the available space. This parameter has no effect on the size of shared memory allocated by PostgreSQL, nor does it reserve kernel disk cache; it is used only for estimation purposes. The default is 128 megabytes (128MB).
18.6.3. Genetic Query Optimizer

geqo (boolean)

Enables or disables genetic query optimization, which is an algorithm that attempts to do query planning without exhaustive searching. This is on by default. The geqo_threshold variable provides a more granular way to disable GEQO for certain classes of queries.

geqo_threshold (integer)

Use genetic query optimization to plan queries with at least this many FROM items involved. (Note that a FULL OUTER JOIN construct counts as only one FROM item.) The default is 12. For simpler queries it is usually best to use the deterministic, exhaustive planner, but for queries with many tables the deterministic planner takes too long.

gcqo_effort (integer)

Controls the trade off between planning time and query plan efficiency in GEQO. This variable must be an integer in the range from 1 to 10. The default value is five. Larger values increase the time spent doing query planning, but also increase the likelihood that an efficient query plan will be chosen.

gcqo_effort doesn’t actually do anything directly; it is only used to compute the default values for the other variables that influence GEQO behavior (described below). If you prefer, you can set the other parameters by hand instead.

gcqo_pool_size (integer)

Controls the pool size used by GEQO. The pool size is the number of individuals in the genetic population. It must be at least two, and useful values are typically 100 to 1000. If it is set to zero (the default setting) then a suitable default is chosen based on gcqo_effort and the number of tables in the query.

gcqo_generations (integer)

Controls the number of generations used by GEQO. Generations specifies the number of iterations of the algorithm. It must be at least one, and useful values are in the same range as the pool size. If it is set to zero (the default setting) then a suitable default is chosen based on gcqo_pool_size.

gcqo_selection_bias (floating point)

Controls the selection bias used by GEQO. The selection bias is the selective pressure within the population. Values can be from 1.50 to 2.00; the latter is the default.

18.6.4. Other Planner Options

default_statistics_target (integer)

Sets the default statistics target for table columns that have not had a column-specific target set via ALTER TABLE SET STATISTICS. Larger values increase the time needed to do ANALYZE, but might improve the quality of the planner’s estimates. The default is 10. For more information on the use of statistics by the PostgreSQL query planner, refer to Section 14.2.

constraint_exclusion (boolean)

Enables or disables the query planner’s use of table constraints to optimize queries. The default is off.
When this parameter is on, the planner compares query conditions with table CHECK constraints, and omits scanning tables for which the conditions contradict the constraints. For example:

CREATE TABLE parent(key integer, ...);
CREATE TABLE child1000(check (key between 1000 and 1999)) INHERITS(parent);
CREATE TABLE child2000(check (key between 2000 and 2999)) INHERITS(parent);
...
SELECT * FROM parent WHERE key = 2400;

With constraint exclusion enabled, this SELECT will not scan child1000 at all. This can improve performance when inheritance is used to build partitioned tables.

Currently, constraint_exclusion is disabled by default because the constraint checks are relatively expensive, and in many circumstances will yield no savings. It is recommended to turn this on only if you are actually using partitioned tables designed to take advantage of the feature.

Refer to Section 5.9 for more information on using constraint exclusion and partitioning.

from_collapse_limit (integer)

The planner will merge sub-queries into upper queries if the resulting FROM list would have no more than this many items. Smaller values reduce planning time but might yield inferior query plans. The default is eight. It is usually wise to keep this less than geqo_threshold. For more information see Section 14.3.

join_collapse_limit (integer)

The planner will rewrite explicit JOIN constructs (except FULL JOINS) into lists of FROM items whenever a list of no more than this many items would result. Smaller values reduce planning time but might yield inferior query plans.

By default, this variable is set the same as from_collapse_limit, which is appropriate for most uses. Setting it to 1 prevents any reordering of explicit JOINS. Thus, the explicit join order specified in the query will be the actual order in which the relations are joined. The query planner does not always choose the optimal join order; advanced users can elect to temporarily set this variable to 1, and then specify the join order they desire explicitly. For more information see Section 14.3.

18.7. Error Reporting and Logging

18.7.1. Where To Log

log_destination (string)

PostgreSQL supports several methods for logging server messages, including stderr, csvlog and syslog. On Windows, eventlog is also supported. Set this parameter to a list of desired log destinations separated by commas. The default is to log to stderr only. This parameter can only be set in the postgresql.conf file or on the server command line.

If csvlog is included in log_destination, log entries are output in “comma separated value” format, which is convenient for loading them into programs. See Section 18.7.4 for details. logging_collector must be enabled to generate CSV-format log output.

Note: On most Unix systems, you will need to alter the configuration of your system’s syslog daemon in order to make use of the syslog option for log_destination. PostgreSQL can log
to syslog facilities \texttt{LOCAL0} through \texttt{LOCAL7} (see syslog\_facility), but the default syslog configuration on most platforms will discard all such messages. You will need to add something like

\texttt{local0.* /var/log/postgresql}

to the syslog daemon’s configuration file to make it work.

\textbf{logging\_collector} (boolean)

This parameter allows messages sent to stderr, and CSV-format log output, to be captured and redirected into log files. This approach is often more useful than logging to syslog, since some types of messages might not appear in syslog output (a common example is dynamic-linker failure messages). This parameter can only be set at server start.

\textbf{log\_directory} (string)

When \textbf{logging\_collector} is enabled, this parameter determines the directory in which log files will be created. It can be specified as an absolute path, or relative to the cluster data directory. This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.

\textbf{log\_filename} (string)

When \textbf{logging\_collector} is enabled, this parameter sets the file names of the created log files. The value is treated as a strftime pattern, so %-escapes can be used to specify time-varying file names. (Note that if there are any time-zone-dependent %-escapes, the computation is done in the zone specified by \texttt{log\_timezone}.) If no %-escapes are present, PostgreSQL will append the epoch of the new log file’s creation time. For example, if \texttt{log\_filename} were \texttt{server\_log}, then the chosen file name would be \texttt{server\_log.1093827753} for a log starting at Sun Aug 29 19:02:33 2004 MST. This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.

If CSV-format output is enabled in \textbf{log\_destination}, .csv will be appended to the times-tamped log file name to create the file name for CSV-format output. (If \texttt{log\_filename} ends in .log, the suffix is replaced instead.) In the case of the example above, the CSV file name will be \texttt{server\_log.1093827753.csv}.

\textbf{log\_rotation\_age} (integer)

When \textbf{logging\_collector} is enabled, this parameter determines the maximum lifetime of an individual log file. After this many minutes have elapsed, a new log file will be created. Set to zero to disable time-based creation of new log files. This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.

\textbf{log\_rotation\_size} (integer)

When \textbf{logging\_collector} is enabled, this parameter determines the maximum size of an individual log file. After this many kilobytes have been emitted into a log file, a new log file will be created. Set to zero to disable size-based creation of new log files. This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.

\textbf{log\_truncate\_on\_rotation} (boolean)

When \textbf{logging\_collector} is enabled, this parameter will cause PostgreSQL to truncate (overwrite), rather than append to, any existing log file of the same name. However, truncation will occur only when a new file is being opened due to time-based rotation, not during server startup or size-based rotation. When off, pre-existing files will be appended to in all cases. For example, using this setting in combination with a \texttt{log\_filename} like \texttt{postgresql-\%H.log} would result in generating twenty-four hourly log files and then cyclically overwriting them. This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.
Example: To keep 7 days of logs, one log file per day named `server_log.Mon, server_log.Tue`, etc, and automatically overwrite last week’s log with this week’s log, set `log_filename` to `server_log.%a`, `log_truncate_on_rotation` to `on`, and `log_rotation_age` to `1440`.

Example: To keep 24 hours of logs, one log file per hour, but also rotate sooner if the log file size exceeds 1GB, set `log_filename` to `server_log.%H%M`, `log_truncate_on_rotation` to `on`, `log_rotation_age` to `60`, and `log_rotation_size` to `1000000`. Including `%M` in `log_filename` allows any size-driven rotations that might occur to select a file name different from the hour’s initial file name.

`syslog_facility` (string)

When logging to syslog is enabled, this parameter determines the syslog “facility” to be used. You can choose from `LOCAL0`, `LOCAL1`, `LOCAL2`, `LOCAL3`, `LOCAL4`, `LOCAL5`, `LOCAL6`, `LOCAL7`; the default is `LOCAL0`. See also the documentation of your system’s syslog daemon. This parameter can only be set in the `postgresql.conf` file or on the server command line. This parameter is unavailable unless the server is compiled with support for syslog.

`syslog_ident` (string)

When logging to syslog is enabled, this parameter determines the program name used to identify PostgreSQL messages in syslog logs. The default is `postgres`. This parameter can only be set in the `postgresql.conf` file or on the server command line. This parameter is unavailable unless the server is compiled with support for syslog.

### 18.7.2. When To Log

`client_min_messages` (string)

Controls which message levels are sent to the client. Valid values are `DEBUG5`, `DEBUG4`, `DEBUG3`, `DEBUG2`, `DEBUG1`, `LOG`, `NOTICE`, `WARNING`, `ERROR`, `FATAL`, and `PANIC`. Each level includes all the levels that follow it. The later the level, the fewer messages are sent. The default is `NOTICE`. Note that `LOG` has a different rank here than in `log_min_messages`.

`log_min_messages` (string)

Controls which message levels are written to the server log. Valid values are `DEBUG5`, `DEBUG4`, `DEBUG3`, `DEBUG2`, `DEBUG1`, `INFO`, `NOTICE`, `WARNING`, `ERROR`, `LOG`, `FATAL`, and `PANIC`. Each level includes all the levels that follow it. The later the level, the fewer messages are sent to the log. The default is `NOTICE`. Note that `LOG` has a different rank here than in `client_min_messages`. Only superusers can change this setting.

`log_error_verbosity` (string)

Controls the amount of detail written in the server log for each message that is logged. Valid values are `TERSE`, `DEFAULT`, and `VERBOSE`, each adding more fields to displayed messages. Only superusers can change this setting.

`log_min_error_statement` (string)

Controls whether or not the SQL statement that causes an error condition will be recorded in the server log. The current SQL statement is included in the log entry for any message of the specified severity or higher. Valid values are `DEBUG5`, `DEBUG4`, `DEBUG3`, `DEBUG2`, `DEBUG1`, `INFO`, `NOTICE`, `WARNING`, `ERROR`, `LOG`, `FATAL`, and `PANIC`. The default is `ERROR`, which means statements causing errors, log messages, fatal errors, or panics will be logged. To effectively turn
off logging of failing statements, set this parameter to PANIC. Only superusers can change this setting.

log_min_duration_statement (integer)

Causes the duration of each completed statement to be logged if the statement ran for at least the specified number of milliseconds. Setting this to zero prints all statement durations. Minus-one (the default) disables logging statement durations. For example, if you set it to 250ms then all SQL statements that run 250ms or longer will be logged. Enabling this parameter can be helpful in tracking down unoptimized queries in your applications. Only superusers can change this setting.

For clients using extended query protocol, durations of the Parse, Bind, and Execute steps are logged independently.

**Note:** When using this option together with log_statement, the text of statements that are logged because of log_statement will not be repeated in the duration log message. If you are not using syslog, it is recommended that you log the PID or session ID using log_line_prefix so that you can link the statement message to the later duration message using the process ID or session ID.

silent_mode (boolean)

Runs the server silently. If this parameter is set, the server will automatically run in background and any controlling terminals are disassociated. The server’s standard output and standard error are redirected to /dev/null, so any messages sent to them will be lost. Unless syslog logging is selected or logging_collector is enabled, using this parameter is discouraged because it makes it impossible to see error messages. This parameter can only be set at server start.

Table 18-1 explains the message severity levels used by PostgreSQL. If logging output is sent to syslog or Windows’ eventlog, the severity levels are translated as shown in the table.

**Table 18-1. Message severity levels**

<table>
<thead>
<tr>
<th>Severity</th>
<th>Usage</th>
<th>syslog</th>
<th>eventlog</th>
</tr>
</thead>
<tbody>
<tr>
<td>DEBUG1..DEBUG5</td>
<td>Provides successively-more-detailed information for use by developers.</td>
<td>DEBUG</td>
<td>INFORMATION</td>
</tr>
<tr>
<td>INFO</td>
<td>Provides information implicitly requested by the user, e.g., output from VACUUMVERBOSE.</td>
<td>INFO</td>
<td>INFORMATION</td>
</tr>
<tr>
<td>NOTICE</td>
<td>Provides information that might be helpful to users, e.g., notice of truncation of long identifiers.</td>
<td>NOTICE</td>
<td>INFORMATION</td>
</tr>
<tr>
<td>WARNING</td>
<td>Provides warnings of likely problems, e.g., COMMIT outside a transaction block.</td>
<td>NOTICE</td>
<td>WARNING</td>
</tr>
</tbody>
</table>
### Chapter 18. Server Configuration

<table>
<thead>
<tr>
<th>Severity</th>
<th>Usage</th>
<th>syslog</th>
<th>eventlog</th>
</tr>
</thead>
<tbody>
<tr>
<td>ERROR</td>
<td>Reports an error that caused the current command to abort.</td>
<td>WARNING</td>

<tr>
<td>FATAL</td>
<td>Reports an error that caused the current session to abort.</td>
<td>ERR</td>
<td>ERROR</td>
</tr>
<tr>
<td>PANIC</td>
<td>Reports an error that caused all database sessions to abort.</td>
<td>CRIT</td>
<td>ERROR</td>
</tr>
</tbody>
</table>

### 18.7.3. What To Log

**debug_print_parse**(boolean)

**debug_print_rewritten**(boolean)

**debug_print_plan**(boolean)

**debug_pretty_print**(boolean)

These parameters enable various debugging output to be emitted. For each executed query, they print the resulting parse tree, the query rewriter output, or the execution plan. **debug_pretty_print** indents these displays to produce a more readable but much longer output format. **client_min_messages** or **log_min_messages** must be **DEBUG1** or lower to actually send this output to the client or the server log, respectively. These parameters are off by default.

**log_checkpoints**(boolean)

Causes checkpoints to be logged in the server log. Some statistics about each checkpoint are included in the log messages, including the number of buffers written and the time spent writing them. This parameter can only be set in the **postgresql.conf** file or on the server command line. The default is off.

**log_connections**(boolean)

Causes each attempted connection to the server to be logged, as well as successful completion of client authentication. This parameter can only be set in the **postgresql.conf** file or on the server command line. The default is off.

**Note:** Some client programs, like psql, attempt to connect twice while determining if a password is required, so duplicate “connection received” messages do not necessarily indicate a problem.

**log_disconnections**(boolean)

This outputs a line in the server log similar to **log_connections** but at session termination, and includes the duration of the session. This is off by default. This parameter can only be set in the **postgresql.conf** file or on the server command line.
log_duration (boolean)

Causes the duration of every completed statement to be logged. The default is off. Only superusers can change this setting.

For clients using extended query protocol, durations of the Parse, Bind, and Execute steps are logged independently.

Note: The difference between setting this option and setting log_min_duration_statement to zero is that exceeding log_min_duration_statement forces the text of the query to be logged, but this option doesn’t. Thus, if log_duration is on and log_min_duration_statement has a positive value, all durations are logged but the query text is included only for statements exceeding the threshold. This behavior can be useful for gathering statistics in high-load installations.

log_hostname (boolean)

By default, connection log messages only show the IP address of the connecting host. Turning on this parameter causes logging of the host name as well. Note that depending on your host name resolution setup this might impose a non-negligible performance penalty. This parameter can only be set in the postgresql.conf file or on the server command line.

log_line_prefix (string)

This is a printf-style string that is output at the beginning of each log line. % characters begin “escape sequences” that are replaced with status information as outlined below. Unrecognized escapes are ignored. Other characters are copied straight to the log line. Some escapes are only recognized by session processes, and do not apply to background processes such as the main server process. This parameter can only be set in the postgresql.conf file or on the server command line. The default is an empty string.

<table>
<thead>
<tr>
<th>Escape</th>
<th>Effect</th>
<th>Session only</th>
</tr>
</thead>
<tbody>
<tr>
<td>%u</td>
<td>User name</td>
<td>yes</td>
</tr>
<tr>
<td>%d</td>
<td>Database name</td>
<td>yes</td>
</tr>
<tr>
<td>%r</td>
<td>Remote host name or IP address, and remote port</td>
<td>yes</td>
</tr>
<tr>
<td>%h</td>
<td>Remote host name or IP address</td>
<td>yes</td>
</tr>
<tr>
<td>%p</td>
<td>Process ID</td>
<td>no</td>
</tr>
<tr>
<td>%t</td>
<td>Time stamp without milliseconds</td>
<td>no</td>
</tr>
<tr>
<td>%m</td>
<td>Time stamp with milliseconds</td>
<td>no</td>
</tr>
<tr>
<td>%i</td>
<td>Command tag: type of session’s current command</td>
<td>yes</td>
</tr>
<tr>
<td>%c</td>
<td>Session ID: see below</td>
<td>no</td>
</tr>
<tr>
<td>%l</td>
<td>Number of the log line for each session or process, starting at 1</td>
<td>no</td>
</tr>
<tr>
<td>%s</td>
<td>Process start time stamp</td>
<td>no</td>
</tr>
<tr>
<td>%v</td>
<td>Virtual transaction ID (backendID/localXID)</td>
<td>no</td>
</tr>
</tbody>
</table>
Chapter 18. Server Configuration

### Escape

<table>
<thead>
<tr>
<th>Escape</th>
<th>Effect</th>
<th>Session only</th>
</tr>
</thead>
<tbody>
<tr>
<td>%x</td>
<td>Transaction ID (0 if none is assigned)</td>
<td>no</td>
</tr>
<tr>
<td>%q</td>
<td>Produces no output, but tells non-session processes to stop at this point in the string; ignored by session processes</td>
<td>no</td>
</tr>
<tr>
<td>%%</td>
<td>Literal %</td>
<td>no</td>
</tr>
</tbody>
</table>

The `%c` escape prints a quasi-unique session identifier, consisting of two 4-byte hexadecimal numbers (without leading zeros) separated by a dot. The numbers are the process start time and the process ID, so `%c` can also be used as a space saving way of printing those items.

**Tip:** If you set a nonempty value for `log_line_prefix`, you should usually make its last character be a space, to provide visual separation from the rest of the log line. A punctuation character could be used too.

**Tip:** Syslog produces its own time stamp and process ID information, so you probably do not want to use those escapes if you are logging to syslog.

---

**log_lock_waits (boolean)**

Controls whether a log message is produced when a session waits longer than `deadlock_timeout` to acquire a lock. This is useful in determining if lock waits are causing poor performance. The default is `off`.

**log_statement (string)**

Controls which SQL statements are logged. Valid values are `none`, `ddl`, `mod`, and `all`. `ddl` logs all data definition statements, such as `CREATE`, `ALTER`, and `DROP` statements. `mod` logs all `ddl` statements, plus data-modifying statements such as `INSERT`, `UPDATE`, `DELETE`, `TRUNCATE`, and `COPY FROM`, `PREPARE`, `EXECUTE`, and `EXPLAIN ANALYZE` statements are also logged if their contained command is of an appropriate type. For clients using extended query protocol, logging occurs when an `Execute` message is received, and values of the Bind parameters are included (with any embedded single-quote marks doubled).

The default is `none`. Only superusers can change this setting.

**Note:** Statements that contain simple syntax errors are not logged even by the `log_statement = all` setting, because the log message is emitted only after basic parsing has been done to determine the statement type. In the case of extended query protocol, this setting likewise does not log statements that fail before the `Execute` phase (i.e., during parse analysis or planning). Set `log_min_error_statement` to `ERROR` (or lower) to log such statements.

**log_temp_files (integer)**

Controls whether temporary files are logged when deleted. Temporary files can be created for sorts, hashes, and temporary query results. A value of zero logs all temporary files, and positive values log only files whose size is equal or greater than the specified number of kilobytes. The default is `-1`, which disables this logging.
log_timezone (string)

Sets the time zone used for timestamps written in the log. Unlike timezone, this value is cluster-wide, so that all sessions will report timestamps consistently. The default is unknown, which means to use whatever the system environment specifies as the time zone. See Section 8.5.3 for more information. This parameter can only be set in the postgresql.conf file or on the server command line.

18.7.4. Using CSV-Format Log Output

Including csvlog in the log_destination list provides a convenient way to import log files into a database table. This option emits log lines in comma-separated-value format, with these columns: timestamp with milliseconds, user name, database name, process ID, host:port number, session ID, per-session or -process line number, command tag, session start time, virtual transaction ID, regular transaction id, error severity, SQL state code, error message, error message detail, hint, internal query that led to the error (if any), character count of the error position thereof, error context, user query that led to the error (if any and enabled by log_min_error_statement), character count of the error position thereof, location of the error in the PostgreSQL source code (if log_error_verbosity is set to verbose). Here is a sample table definition for storing CSV-format log output:

```
CREATE TABLE postgres_log
(
  log_time timestamp(3) with time zone,
  user_name text,
  database_name text,
  process_id integer,
  connection_from text,
  session_id text,
  session_line_num bigint,
  command_tag text,
  session_start_time timestamp with time zone,
  virtual_transaction_id text,
  transaction_id bigint,
  error_severity text,
  sql_state_code text,
  message text,
  detail text,
  hint text,
  internal_query text,
  internal_query_pos integer,
  context text,
  query text,
  query_pos integer,
  location text,
  PRIMARY KEY (session_id, session_line_num)
);
```

To import a log file into this table, use the COPY FROM command:

```
COPY postgres_log FROM '/full/path/to/logfile.csv' WITH csv;
```

There are a few things you need to do to simplify importing CSV log files easily and automatically:
1. Set `log_filename` and `log_rotation_age` to provide a consistent, predictable naming scheme for your log files. This lets you predict what the file name will be and know when an individual log file is complete and therefore ready to be imported.

2. Set `log_rotation_size` to 0 to disable size-based log rotation, as it makes the log file name difficult to predict.

3. Set `log_truncate_on_rotation` to `on` so that old log data isn’t mixed with the new in the same file.

4. The table definition above includes a primary key specification. This is useful to protect against accidentally importing the same information twice. The `COPY` command commits all of the data it imports at one time, so any error will cause the entire import to fail. If you import a partial log file and later import the file again when it is complete, the primary key violation will cause the import to fail. Wait until the log is complete and closed before importing. This procedure will also protect against accidentally importing a partial line that hasn’t been completely written, which would also cause `COPY` to fail.

### 18.8. Run-Time Statistics

#### 18.8.1. Query and Index Statistics Collector

These parameters control server-wide statistics collection features. When statistics collection is enabled, the data that is produced can be accessed via the `pg_stat` and `pg_statio` family of system views. Refer to Chapter 26 for more information.

- `track_activities` (boolean)
  Enables the collection of information on the currently executing command of each session, along with the time at which that command began execution. This parameter is on by default. Note that even when enabled, this information is not visible to all users, only to superusers and the user owning the session being reported on; so it should not represent a security risk. Only superusers can change this setting.

- `track_counts` (boolean)
  Enables collection of statistics on database activity. This parameter is on by default, because the autovacuum daemon needs the collected information. Only superusers can change this setting.

- `update_process_title` (boolean)
  Enables updating of the process title every time a new SQL command is received by the server. The process title is typically viewed by the `ps` command, or in Windows by using the Process Explorer. Only superusers can change this setting.
Chapter 18. Server Configuration

18.8.2. Statistics Monitoring

log_statement_stats (boolean)
log_parser_stats (boolean)
log_planner_stats (boolean)
log_executor_stats (boolean)

For each query, write performance statistics of the respective module to the server log. This is a crude profiling instrument. log_statement_stats reports total statement statistics, while the others report per-module statistics. log_statement_stats cannot be enabled together with any of the per-module options. All of these options are disabled by default. Only superusers can change these settings.

18.9. Automatic Vacuuming

These settings control the behavior of the autovacuum feature. Refer to Section 23.1.4 for more information.

autovacuum (boolean)

Controls whether the server should run the autovacuum launcher daemon. This is on by default; however, track_counts must also be turned on for autovacuum to work. This parameter can only be set in the postgresql.conf file or on the server command line.

Note that even when this parameter is disabled, the system will launch autovacuum processes if necessary to prevent transaction ID wraparound. See Section 23.1.3 for more information.

log_autovacuum_min_duration (integer)

Causes each action executed by autovacuum to be logged if it ran for at least the specified number of milliseconds. Setting this to zero logs all autovacuum actions. Minus-one (the default) disables logging autovacuum actions. For example, if you set this to 250ms then all automatic vacuums and analyzes that run 250ms or longer will be logged. Enabling this parameter can be helpful in tracking autovacuum activity. This setting can only be set in the postgresql.conf file or on the server command line.

autovacuum_max_workers (integer)

Specifies the maximum number of autovacuum processes (other than the autovacuum launcher) which may be running at any one time. The default is three. This parameter can only be set in the postgresql.conf file or on the server command line.

autovacuum_naptime (integer)

Specifies the minimum delay between autovacuum runs on any given database. In each round the daemon examines the database and issues VACUUM and ANALYZE commands as needed for tables in that database. The delay is measured in seconds, and the default is one minute (1m). This parameter can only be set in the postgresql.conf file or on the server command line.

autovacuum_vacuum_threshold (integer)

Specifies the minimum number of updated or deleted tuples needed to trigger a VACUUM in any one table. The default is 50 tuples. This parameter can only be set in the postgresql.conf file or on the server command line. This setting can be overridden for individual tables by entries in pg_autovacuum.
autovacuum_analyze_threshold (integer)

Specifies the minimum number of inserted, updated or deleted tuples needed to trigger an ANALYZE in any one table. The default is 50 tuples. This parameter can only be set in the postgresql.conf file or on the server command line. This setting can be overridden for individual tables by entries in pg_autovacuum.

autovacuum_vacuum_scale_factor (floating point)

Specifies a fraction of the table size to add to autovacuum_vacuum_threshold when deciding whether to trigger a VACUUM. The default is 0.2 (20% of table size). This parameter can only be set in the postgresql.conf file or on the server command line. This setting can be overridden for individual tables by entries in pg_autovacuum.

autovacuum_analyze_scale_factor (floating point)

Specifies a fraction of the table size to add to autovacuum_analyze_threshold when deciding whether to trigger an ANALYZE. The default is 0.1 (10% of table size). This parameter can only be set in the postgresql.conf file or on the server command line. This setting can be overridden for individual tables by entries in pg_autovacuum.

autovacuum_freeze_max_age (integer)

Specifies the maximum age (in transactions) that a table’s pg_class.relro frozenxid field can attain before a VACUUM operation is forced to prevent transaction ID wraparound within the table. Note that the system will launch autovacuum processes to prevent wraparound even when autovacuum is otherwise disabled. The default is 200 million transactions. This parameter can only be set at server start, but the setting can be reduced for individual tables by entries in pg_autovacuum. For more information see Section 23.1.3.

autovacuum_vacuum_cost_delay (integer)

Specifies the cost delay value that will be used in automatic VACUUM operations. If -1 is specified, the regular vacuum_cost_delay value will be used. The default value is 20 milliseconds. This parameter can only be set in the postgresql.conf file or on the server command line. This setting can be overridden for individual tables by entries in pg_autovacuum.

autovacuum_vacuum_cost_limit (integer)

Specifies the cost limit value that will be used in automatic VACUUM operations. If -1 is specified (which is the default), the regular vacuum_cost_limit value will be used. Note that the value is distributed proportionally among the running autovacuum workers, if there is more than one, so that the sum of the limits of each worker never exceeds the limit on this variable. This parameter can only be set in the postgresql.conf file or on the server command line. This setting can be overridden for individual tables by entries in pg_autovacuum.

18.10. Client Connection Defaults

18.10.1. Statement Behavior

search_path (string)

This variable specifies the order in which schemas are searched when an object (table, data type, function, etc.) is referenced by a simple name with no schema component. When there are objects of identical names in different schemas, the one found first in the search path is used. An
object that is not in any of the schemas in the search path can only be referenced by specifying
tits containing schema with a qualified (dotted) name.

The value for search_path has to be a comma-separated list of schema names. If one of the list
items is the special value $user, then the schema having the name returned by SESSION_USER
is substituted, if there is such a schema. (If not, $user is ignored.)

The system catalog schema, pg_catalog, is always searched, whether it is mentioned in the
path or not. If it is mentioned in the path then it will be searched in the specified order. If
pg_catalog is not in the path then it will be searched before searching any of the path items.

Likewise, the current session’s temporary-table schema, pg_temp_nnn, is always searched if it
exists. It can be explicitly listed in the path by using the alias pg_temp. If it is not listed in the
path then it is searched first (before even pg_catalog). However, the temporary schema is only
searched for relation (table, view, sequence, etc) and data type names. It will never be searched
for function or operator names.

When objects are created without specifying a particular target schema, they will be placed in
the first schema listed in the search path. An error is reported if the search path is empty.

The default value for this parameter is ‘"$user", public’ (where the second part will be
ignored if there is no schema named public). This supports shared use of a database (where
no users have private schemas, and all share use of public), private per-user schemas, and
combinations of these. Other effects can be obtained by altering the default search path setting,
either globally or per-user.

The current effective value of the search path can be examined via the SQL function
current_schemas(). This is not quite the same as examining the value of search_path,
since current_schemas() shows how the requests appearing in search_path were
resolved.

For more information on schema handling, see Section 5.7.

default_tablespace (string)

This variable specifies the default tablespace in which to create objects (tables and indexes) when
a CREATE command does not explicitly specify a tablespace.

The value is either the name of a tablespace, or an empty string to specify using the default ta-
blespace of the current database. If the value does not match the name of any existing tablespace,
PostgreSQL will automatically use the default tablespace of the current database. If a nondefault
tablespace is specified, the user must have CREATE privilege for it, or creation attempts will fail.

This variable is not used for temporary tables; for them, temp_tablespaces is consulted instead.

For more information on tablespaces, see Section 20.6.

temp_tablespaces (string)

This variable specifies tablespace(s) in which to create temporary objects (temp tables and in-
dexes on temp tables) when a CREATE command does not explicitly specify a tablespace. Temp-
orary files for purposes such as sorting large data sets are also created in these tablespace(s).

The value is a list of names of tablespaces. When there is more than one name in the list, Post-
greSQL chooses a random member of the list each time a temporary object is to be created;
except that within a transaction, successively created temporary objects are placed in successive
tablespaces from the list. If the selected element of the list is an empty string, PostgreSQL will
automatically use the default tablespace of the current database instead.

When temp_tablespaces is set interactively, specifying a nonexistent tablespace is an er-
ror, as is specifying a tablespace for which the user does not have CREATE privilege. However,
when using a previously set value, nonexistent tablespaces are ignored, as are tablespaces for which the user lacks CREATE privilege. In particular, this rule applies when using a value set in postgresql.conf.

The default value is an empty string, which results in all temporary objects being created in the default tablespace of the current database.

See also default_tablespace.

cHECK_FUNCTION_BODIES (boolean)

This parameter is normally on. When set to off, it disables validation of the function body string during CREATE FUNCTION. Disabling validation is occasionally useful to avoid problems such as forward references when restoring function definitions from a dump.

default_transaction_isolation (string)

Each SQL transaction has an isolation level, which can be either “read uncommitted”, “read committed”, “repeatable read”, or “serializable”. This parameter controls the default isolation level of each new transaction. The default is “read committed”.

Consult Chapter 13 and SET TRANSACTION for more information.

default_transaction_read_only (boolean)

A read-only SQL transaction cannot alter non-temporary tables. This parameter controls the default read-only status of each new transaction. The default is off (read/write).

Consult SET TRANSACTION for more information.

SESSION_REPLICATION_ROLE (string)

Controls firing of replication-related triggers and rules for the current session. Setting this variable requires superuser privilege and results in discarding any previously cached query plans. Possible values are origin (the default), replica and local. See ALTER TABLE for more information.

STATEMENT_TIMEOUT (integer)

Abort any statement that takes over the specified number of milliseconds, starting from the time the command arrives at the server from the client. If log_min_error_statement is set to ERROR or lower, the statement that timed out will also be logged. A value of zero (the default) turns off the limitation.

Setting statement_timeout in postgresql.conf is not recommended because it affects all sessions.

VACUUM_FREEZE_MIN_AGE (integer)

Specifies the cutoff age (in transactions) that VACUUM should use to decide whether to replace transaction IDs with FrozenXID while scanning a table. The default is 100 million transactions. Although users can set this value anywhere from zero to one billion, VACUUM will silently limit the effective value to half the value of autovacuum_freeze_max_age, so that there is not an unreasonably short time between forced autovacuums. For more information see Section 23.1.3.

XML_BINARY (string)

Sets how binary values are to be encoded in XML. This applies for example when bytea values are converted to XML by the functions xmlelement or xmlforest. Possible values are base64 and hex, which are both defined in the XML Schema standard. The default is base64. For further information about XML-related functions, see Section 9.14.
The actual choice here is mostly a matter of taste, constrained only by possible restrictions in client applications. Both methods support all possible values, although the hex encoding will be somewhat larger than the base64 encoding.

**xmlOption** (string)

Sets whether `DOCUMENT` or `CONTENT` is implicit when converting between XML and character string values. See Section 8.13 for a description of this. Valid values are `DOCUMENT` and `CONTENT`. The default is `CONTENT`.

According to the SQL standard, the command to set this option is

```sql
SET XML OPTION { DOCUMENT | CONTENT };
```

This syntax is also available in PostgreSQL.

### 18.10.2. Locale and Formatting

**DateStyle** (string)

Sets the display format for date and time values, as well as the rules for interpreting ambiguous date input values. For historical reasons, this variable contains two independent components: the output format specification (`ISO`, `Postgres`, `SQL`, or `German`) and the input/output specification for year/month/day ordering (`DMY`, `MDY`, or `YMD`). These can be set separately or together. The keywords `Euro` and `European` are synonyms for `DMY`; the keywords `US`, `NonEuro`, and `NonEuropean` are synonyms for `MDY`. See Section 8.5 for more information. The built-in default is `ISO`, `MDY`, but `initdb` will initialize the configuration file with a setting that corresponds to the behavior of the chosen `lc_time` locale.

**timezone** (string)

Sets the time zone for displaying and interpreting time stamps. The default is `unknown`, which means to use whatever the system environment specifies as the time zone. See Section 8.5.3 for more information.

**timezone_abbreviations** (string)

Sets the collection of time zone abbreviations that will be accepted by the server for datetime input. The default is ‘Default’, which is a collection that works in most of the world; there are also ‘Australia’ and ‘India’, and other collections can be defined for a particular installation. See Appendix B for more information.

**extra_float_digits** (integer)

This parameter adjusts the number of digits displayed for floating-point values, including `float4`, `float8`, and geometric data types. The parameter value is added to the standard number of digits (`FLT_DIG` or `DBL_DIG` as appropriate). The value can be set as high as 2, to include partially-significant digits; this is especially useful for dumping float data that needs to be restored exactly. Or it can be set negative to suppress unwanted digits.

**client_encoding** (string)

Sets the client-side encoding (character set). The default is to use the database encoding.

**lc_messages** (string)

Sets the language in which messages are displayed. Acceptable values are system-dependent; see Section 22.1 for more information. If this variable is set to the empty string (which is the default) then the value is inherited from the execution environment of the server in a system-dependent way.
On some systems, this locale category does not exist. Setting this variable will still work, but there will be no effect. Also, there is a chance that no translated messages for the desired language exist. In that case you will continue to see the English messages.

Only superusers can change this setting, because it affects the messages sent to the server log as well as to the client.

**lc_monetary(string)**

Sets the locale to use for formatting monetary amounts, for example with the `to_char` family of functions. Acceptable values are system-dependent; see Section 22.1 for more information. If this variable is set to the empty string (which is the default) then the value is inherited from the execution environment of the server in a system-dependent way.

**lc_numeric(string)**

Sets the locale to use for formatting numbers, for example with the `to_char` family of functions. Acceptable values are system-dependent; see Section 22.1 for more information. If this variable is set to the empty string (which is the default) then the value is inherited from the execution environment of the server in a system-dependent way.

**lc_time(string)**

Sets the locale to use for formatting date and time values. (Currently, this setting does nothing, but it might in the future.) Acceptable values are system-dependent; see Section 22.1 for more information. If this variable is set to the empty string (which is the default) then the value is inherited from the execution environment of the server in a system-dependent way.

**default_text_search_config(string)**

Selects the text search configuration that is used by those variants of the text search functions that do not have an explicit argument specifying the configuration. See Chapter 12 for further information. The built-in default is `pg_catalog.simple`, but `initdb` will initialize the configuration file with a setting that corresponds to the chosen `lc_ctype` locale, if a configuration matching that locale can be identified.

### 18.10.3. Other Defaults

**explain_pretty_print(boolean)**

Determines whether `EXPLAIN VERBOSE` uses the indented or non-indented format for displaying detailed query-tree dumps. The default is `on`.

**dynamic_library_path(string)**

If a dynamically loadable module needs to be opened and the file name specified in the `CREATE FUNCTION` or `LOAD` command does not have a directory component (i.e. the name does not contain a slash), the system will search this path for the required file.

The value for `dynamic_library_path` has to be a list of absolute directory paths separated by colons (or semi-colons on Windows). If a list element starts with the special string `$libdir`, the compiled-in PostgreSQL package library directory is substituted for `$libdir`. This is where the modules provided by the standard PostgreSQL distribution are installed. (Use `pg_config --pkglibdir` to find out the name of this directory.) For example:

- `dynamic_library_path = '/usr/local/lib/postgresql:/home/my_project/lib:$libdir'`
- or, in a Windows environment:
  `dynamic_library_path = 'C:\tools\postgresql;H:\my_project\lib;$libdir'`
The default value for this parameter is `$libdir`. If the value is set to an empty string, the automatic path search is turned off.

This parameter can be changed at run time by superusers, but a setting done that way will only persist until the end of the client connection, so this method should be reserved for development purposes. The recommended way to set this parameter is in the `postgresql.conf` configuration file.

`gin_fuzzy_search_limit (integer)`
Soft upper limit of the size of the set returned by GIN index. For more information see Section 52.4.

`local_preload_libraries (string)`
This variable specifies one or more shared libraries that are to be preloaded at connection start. If more than one library is to be loaded, separate their names with commas. This parameter cannot be changed after the start of a particular session.

Because this is not a superuser-only option, the libraries that can be loaded are restricted to those appearing in the `plugins` subdirectory of the installation’s standard library directory. (It is the database administrator’s responsibility to ensure that only “safe” libraries are installed there.) Entries in `local_preload_libraries` can specify this directory explicitly, for example `$libdir/plugins/mylib`, or just specify the library name — `mylib` would have the same effect as `$libdir/plugins/mylib`.

There is no performance advantage to loading a library at session start rather than when it is first used. Rather, the intent of this feature is to allow debugging or performance-measurement libraries to be loaded into specific sessions without an explicit `LOAD` command being given. For example, debugging could be enabled for all sessions under a given user name by setting this parameter with `ALTER USER SET`.

If a specified library is not found, the connection attempt will fail.

Every PostgreSQL-supported library has a “magic block” that is checked to guarantee compatibility. For this reason, non-PostgreSQL libraries cannot be loaded in this way.

### 18.11. Lock Management

`deadlock_timeout (integer)`
This is the amount of time, in milliseconds, to wait on a lock before checking to see if there is a deadlock condition. The check for deadlock is relatively slow, so the server doesn’t run it every time it waits for a lock. We optimistically assume that deadlocks are not common in production applications and just wait on the lock for a while before starting the check for a deadlock. Increasing this value reduces the amount of time wasted in needless deadlock checks, but slows down reporting of real deadlock errors. The default is one second (`1s`), which is probably about the smallest value you would want in practice. On a heavily loaded server you might want to raise it. Ideally the setting should exceed your typical transaction time, so as to improve the odds that a lock will be released before the waiter decides to check for deadlock.

When `log_lock_waits` is set, this parameter also determines the length of time to wait before a log message is issued about the lock wait. If you are trying to investigate locking delays you might want to set a shorter than normal `deadlock_timeout`. 
max_locks_per_transaction (integer)

The shared lock table is created to track locks on \( \text{max_locks_per_transaction} \) objects (e.g., tables); hence, no more than this many distinct objects can be locked at any one time. This parameter controls the average number of object locks allocated for each transaction; individual transactions can lock more objects as long as the locks of all transactions fit in the lock table. This is not the number of rows that can be locked; that value is unlimited. The default, 64, has historically proven sufficient, but you might need to raise this value if you have clients that touch many different tables in a single transaction. This parameter can only be set at server start.

Increasing this parameter might cause PostgreSQL to request more System V shared memory than your operating system’s default configuration allows. See Section 17.4.1 for information on how to adjust those parameters, if necessary.

18.12. Version and Platform Compatibility

18.12.1. Previous PostgreSQL Versions

add_missing_from (boolean)

When on, tables that are referenced by a query will be automatically added to the FROM clause if not already present. This behavior does not comply with the SQL standard and many people dislike it because it can mask mistakes (such as referencing a table where you should have referenced its alias). The default is off. This variable can be enabled for compatibility with releases of PostgreSQL prior to 8.1, where this behavior was allowed by default.

Note that even when this variable is enabled, a warning message will be emitted for each implicit FROM entry referenced by a query. Users are encouraged to update their applications to not rely on this behavior, by adding all tables referenced by a query to the query’s FROM clause (or its USING clause in the case of DELETE).

array_nulls (boolean)

This controls whether the array input parser recognizes unquoted NULL as specifying a null array element. By default, this is on, allowing array values containing null values to be entered. However, PostgreSQL versions before 8.2 did not support null values in arrays, and therefore would treat NULL as specifying a normal array element with the string value “NULL”. For backwards compatibility with applications that require the old behavior, this variable can be turned off.

Note that it is possible to create array values containing null values even when this variable is off.

backslash_quote (string)

This controls whether a quote mark can be represented by \' in a string literal. The preferred, SQL-standard way to represent a quote mark is by doubling it (\") but PostgreSQL has historically also accepted \'. However, use of \' creates security risks because in some client character set encodings, there are multibyte characters in which the last byte is numerically equivalent to ASCII \'. If client-side code does escaping incorrectly then a SQL-injection attack is possible. This risk can be prevented by making the server reject queries in which a quote mark appears to be escaped by a backslash. The allowed values of backslash_quote are on (allow \' always), off (reject always), and safe_encoding (allow only if client encoding does not allow ASCII \ within a multibyte character). safe_encoding is the default setting.
Note that in a standard-conforming string literal, \ just means \ anyway. This parameter affects the handling of non-standard-conforming literals, including escape string syntax (E’...’).

**default_with_oids (boolean)**

This controls whether CREATE TABLE and CREATE TABLE AS include an OID column in newly-created tables, if neither WITH OIDS nor WITHOUT OIDS is specified. It also determines whether OIDs will be included in tables created by SELECT INTO. In PostgreSQL 8.1 default_with_oids is off by default; in prior versions of PostgreSQL, it was on by default.

The use of OIDs in user tables is considered deprecated, so most installations should leave this variable disabled. Applications that require OIDs for a particular table should specify WITH OIDS when creating the table. This variable can be enabled for compatibility with old applications that do not follow this behavior.

**escape_string_warning (boolean)**

When on, a warning is issued if a backslash (\) appears in an ordinary string literal (‘...’ syntax) and standard_conforming_strings is off. The default is on.

Applications that wish to use backslash as escape should be modified to use escape string syntax (E’...’), because the default behavior of ordinary strings will change in a future release for SQL compatibility. This variable can be enabled to help detect applications that will break.

**regex_flavor (string)**

The regular expression “flavor” can be set to advanced, extended, or basic. The default is advanced. The extended setting might be useful for exact backwards compatibility with pre-7.4 releases of PostgreSQL. See Section 9.7.3.1 for details.

**sql_inheritance (boolean)**

This setting controls whether undecorated table references are considered to include inheritance child tables. The default is on, which means child tables are included (thus, a * suffix is assumed by default). If turned off, child tables are not included (thus, an ONLY prefix is assumed). The SQL standard requires child tables to be included, so the off setting is not spec-compliant, but it is provided for compatibility with PostgreSQL releases prior to 7.1. See Section 5.8 for more information.

Turning sql_inheritance off is deprecated, because behavior has been found to be error-prone as well as contrary to SQL standard. Discussions of inheritance behavior elsewhere in this manual generally assume that it is on.

**standard_conforming_strings (boolean)**

This controls whether ordinary string literals (‘...’) treat backslashes literally, as specified in the SQL standard. The default is currently off, causing PostgreSQL to have its historical behavior of treating backslashes as escape characters. The default will change to on in a future release to improve compatibility with the standard. Applications can check this parameter to determine how string literals will be processed. The presence of this parameter can also be taken as an indication that the escape string syntax (E’...’) is supported. Escape string syntax should be used if an application desires backslashes to be treated as escape characters.

**synchronize_seqscans (boolean)**

This allows sequential scans of large tables to synchronize with each other, so that concurrent scans read the same block at about the same time and hence share the I/O workload. When this is enabled, a scan might start in the middle of the table and then “wrap around” the end to cover all rows, so as to synchronize with the activity of scans already in progress. This can result in unpredictable changes in the row ordering returned by queries that have no ORDER BY clause.
Chapter 18. Server Configuration

Setting this parameter to off ensures the pre-8.3 behavior in which a sequential scan always starts from the beginning of the table. The default is on.

18.12.2. Platform and Client Compatibility

transform_null_equals (boolean)

When on, expressions of the form expr = NULL (or NULL = expr) are treated as expr IS NULL, that is, they return true if expr evaluates to the null value, and false otherwise. The correct SQL-spec-compliant behavior of expr = NULL is to always return null (unknown). Therefore this parameter defaults to off.

However, filtered forms in Microsoft Access generate queries that appear to use expr = NULL to test for null values, so if you use that interface to access the database you might want to turn this option on. Since expressions of the form expr = NULL always return the null value (using the correct interpretation) they are not very useful and do not appear often in normal applications, so this option does little harm in practice. But new users are frequently confused about the semantics of expressions involving null values, so this option is not on by default.

Note that this option only affects the exact form = NULL, not other comparison operators or other expressions that are computationally equivalent to some expression involving the equals operator (such as IN). Thus, this option is not a general fix for bad programming.

Refer to Section 9.2 for related information.

18.13. Preset Options

The following “parameters” are read-only, and are determined when PostgreSQL is compiled or when it is installed. As such, they have been excluded from the sample postgresql.conf file. These options report various aspects of PostgreSQL behavior that might be of interest to certain applications, particularly administrative front-ends.

block_size (integer)

Reports the size of a disk block. It is determined by the value of BLCKSZ when building the server. The default value is 8192 bytes. The meaning of some configuration variables (such as shared_buffers) is influenced by block_size. See Section 18.4 for information.

integer_datetimes (boolean)

Reports whether PostgreSQL was built with support for 64-bit-integer dates and times. It is set by configuring with --enable-integer-datetimes when building PostgreSQL. The default value is off.

lc_collate (string)

Reports the locale in which sorting of textual data is done. See Section 22.1 for more information. The value is determined when the database cluster is initialized.

lc_ctype (string)

Reports the locale that determines character classifications. See Section 22.1 for more information. The value is determined when the database cluster is initialized. Ordinarily this will be the same as lc_collate, but for special applications it might be set differently.
max_function_args (integer)

Reports the maximum number of function arguments. It is determined by the value of
FUNC_MAX_ARGS when building the server. The default value is 100 arguments.

max_identifier_length (integer)

Reports the maximum identifier length. It is determined as one less than the value of
NAMEDATALEN when building the server. The default value of NAMEDATALEN is 64; therefore
the default max_identifier_length is 63 bytes.

max_index_keys (integer)

Reports the maximum number of index keys. It is determined by the value of INDEX_MAX_KEYS
when building the server. The default value is 32 keys.

server_encoding (string)

Reports the database encoding (character set). It is determined when the database is created.
Ordinarily, clients need only be concerned with the value of client_encoding.

server_version (string)

Reports the version number of the server. It is determined by the value of PG_VERSION when
building the server.

server_version_num (integer)

Reports the version number of the server as an integer. It is determined by the value of
PG_VERSION_NUM when building the server.

18.14. Customized Options

This feature was designed to allow parameters not normally known to PostgreSQL to be added by
add-on modules (such as procedural languages). This allows add-on modules to be configured in the
standard ways.

custom_variable_classes (string)

This variable specifies one or several class names to be used for custom variables, in the form
of a comma-separated list. A custom variable is a variable not normally known to PostgreSQL
proper but used by some add-on module. Such variables must have names consisting of a class
name, a dot, and a variable name. custom_variable_classes specifies all the class names in
use in a particular installation. This parameter can only be set in the postgresql.conf file or
on the server command line.

The difficulty with setting custom variables in postgresql.conf is that the file must be read before
add-on modules have been loaded, and so custom variables would ordinarily be rejected as unknown.
When custom_variable_classes is set, the server will accept definitions of arbitrary variables
within each specified class. These variables will be treated as placeholders and will have no function
until the module that defines them is loaded. When a module for a specific class is loaded, it will add
the proper variable definitions for its class name, convert any placeholder values according to those
definitions, and issue warnings for any placeholders of its class that remain (which presumably would
be misspelled configuration variables).

Here is an example of what postgresql.conf might contain when using custom variables:

custom_variable_classes = ‘plr,plperl’
plr.path = ‘/usr/lib/R’
plperl.use_strict = true
plruby.use_strict = true  # generates error: unknown class name

18.15. Developer Options

The following parameters are intended for work on the PostgreSQL source, and in some cases to assist with recovery of severely damaged databases. There should be no reason to use them in a production database setup. As such, they have been excluded from the sample `postgresql.conf` file. Note that many of these parameters require special source compilation flags to work at all.

allow_system_table_mods (boolean)

Allows modification of the structure of system tables. This is used by `initdb`. This parameter can only be set at server start.

debg_assertions (boolean)

Turns on various assertion checks. This is a debugging aid. If you are experiencing strange problems or crashes you might want to turn this on, as it might expose programming mistakes. To use this parameter, the macro `USE_ASSERT_CHECKING` must be defined when PostgreSQL is built (accomplished by the configure option `--enable-cassert`). Note that `debg_assertions` defaults to on if PostgreSQL has been built with assertions enabled.

ignore_system_indexes (boolean)

Ignore system indexes when reading system tables (but still update the indexes when modifying the tables). This is useful when recovering from damaged system indexes. This parameter cannot be changed after session start.

post_auth_delay (integer)

If nonzero, a delay of this many seconds occurs when a new server process is started, after it conducts the authentication procedure. This is intended to give an opportunity to attach to the server process with a debugger. This parameter cannot be changed after session start.

pre_auth_delay (integer)

If nonzero, a delay of this many seconds occurs just after a new server process is forked, before it conducts the authentication procedure. This is intended to give an opportunity to attach to the server process with a debugger to trace down misbehavior in authentication. This parameter can only be set in the `postgresql.conf` file or on the server command line.

trace_notify (boolean)

Generates a great amount of debugging output for the LISTEN and NOTIFY commands. `client_min_messages` or `log_min_messages` must be `DEBUG1` or lower to send this output to the client or server log, respectively.

trace_sort (boolean)

If on, emit information about resource usage during sort operations. This parameter is only available if the `TRACE_SORT` macro was defined when PostgreSQL was compiled. (However, `TRACE_SORT` is currently defined by default.)
trace_locks (boolean)
trace_lwlocks (boolean)
trace_userlocks (boolean)
trace_lock_oidmin (boolean)
trace_lock_table (boolean)
debug_deadlocks (boolean)
log_btree_build_stats (boolean)

Various other code tracing and debugging options.

wal_debug (boolean)

If on, emit WAL-related debugging output. This parameter is only available if the WAL_DEBUG macro was defined when PostgreSQL was compiled.

zero_damaged_pages (boolean)

Detection of a damaged page header normally causes PostgreSQL to report an error, aborting the current command. Setting zero_damaged_pages to on causes the system to instead report a warning, zero out the damaged page, and continue processing. This behavior will destroy data, namely all the rows on the damaged page. But it allows you to get past the error and retrieve rows from any undamaged pages that might be present in the table. So it is useful for recovering data if corruption has occurred due to hardware or software error. You should generally not set this on until you have given up hope of recovering data from the damaged page(s) of a table. The default setting is off, and it can only be changed by a superuser.

### 18.16. Short Options

For convenience there are also single letter command-line option switches available for some parameters. They are described in Table 18-2. Some of these options exist for historical reasons, and their presence as a single-letter option does not necessarily indicate an endorsement to use the option heavily.

<table>

Chapter 19. Database Roles and Privileges

PostgreSQL manages database access permissions using the concept of roles. A role can be thought of as either a database user, or a group of database users, depending on how the role is set up. Roles can own database objects (for example, tables) and can assign privileges on those objects to other roles to control who has access to which objects. Furthermore, it is possible to grant membership in a role to another role, thus allowing the member role use of privileges assigned to the role it is a member of.

The concept of roles subsumes the concepts of “users” and “groups”. In PostgreSQL versions before 8.1, users and groups were distinct kinds of entities, but now there are only roles. Any role can act as a user, a group, or both.

This chapter describes how to create and manage roles and introduces the privilege system. More information about the various types of database objects and the effects of privileges can be found in Chapter 5.

19.1. Database Roles

Database roles are conceptually completely separate from operating system users. In practice it might be convenient to maintain a correspondence, but this is not required. Database roles are global across a database cluster installation (and not per individual database). To create a role use the CREATE ROLE SQL command:

```sql
CREATE ROLE name;
```

`name` follows the rules for SQL identifiers: either unadorned without special characters, or double-quoted. (In practice, you will usually want to add additional options, such as LOGIN, to the command. More details appear below.) To remove an existing role, use the analogous DROP ROLE command:

```sql
DROP ROLE name;
```

For convenience, the programs createuser and dropuser are provided as wrappers around these SQL commands that can be called from the shell command line:

```bash
createuser name
dropuser name
```

To determine the set of existing roles, examine the `pg_roles` system catalog, for example

```sql
SELECT rolname FROM pg_roles;
```

The psql program’s `\du` meta-command is also useful for listing the existing roles.

In order to bootstrap the database system, a freshly initialized system always contains one predefined role. This role is always a “superuser”, and by default (unless altered when running `initdb`) it will have the same name as the operating system user that initialized the database cluster. Customarily, this role will be named `postgres`. In order to create more roles you first have to connect as this initial role.

Every connection to the database server is made in the name of some particular role, and this role determines the initial access privileges for commands issued on that connection. The role name to use for a particular database connection is indicated by the client that is initiating the connection request.
in an application-specific fashion. For example, the \texttt{psql} program uses the \texttt{-U} command line option to indicate the role to connect as. Many applications assume the name of the current operating system user by default (including \texttt{createuser} and \texttt{psql}). Therefore it is often convenient to maintain a naming correspondence between roles and operating system users.

The set of database roles a given client connection can connect as is determined by the client authentication setup, as explained in Chapter 21. (Thus, a client is not necessarily limited to connect as the role with the same name as its operating system user, just as a person’s login name need not match her real name.) Since the role identity determines the set of privileges available to a connected client, it is important to carefully configure this when setting up a multiuser environment.

19.2. Role Attributes

A database role can have a number of attributes that define its privileges and interact with the client authentication system.

login privilege

Only roles that have the \texttt{LOGIN} attribute can be used as the initial role name for a database connection. A role with the \texttt{LOGIN} attribute can be considered the same thing as a “database user”. To create a role with login privilege, use either:

\begin{verbatim}
CREATE ROLE name LOGIN;
CREATE USER name;
\end{verbatim}

(\texttt{CREATE USER} is equivalent to \texttt{CREATE ROLE} except that \texttt{CREATE USER} assumes \texttt{LOGIN} by default, while \texttt{CREATE ROLE} does not.)

superuser status

A database superuser bypasses all permission checks. This is a dangerous privilege and should not be used carelessly; it is best to do most of your work as a role that is not a superuser. To create a new database superuser, use \texttt{CREATE ROLE name SUPERUSER}. You must do this as a role that is already a superuser.

database creation

A role must be explicitly given permission to create databases (except for superusers, since those bypass all permission checks). To create such a role, use \texttt{CREATE ROLE name CREATEDB}.

role creation

A role must be explicitly given permission to create more roles (except for superusers, since those bypass all permission checks). To create such a role, use \texttt{CREATE ROLE name CREATEROLE}. A role with \texttt{CREATEROLE} privilege can alter and drop other roles, too, as well as grant or revoke membership in them. However, to create, alter, drop, or change membership of a superuser role, superuser status is required; \texttt{CREATEROLE} is not sufficient for that.

password

A password is only significant if the client authentication method requires the user to supply a password when connecting to the database. The \texttt{password}, \texttt{md5}, and \texttt{crypt} authentication methods make use of passwords. Database passwords are separate from operating system passwords. Specify a password upon role creation with \texttt{CREATE ROLE name PASSWORD ‘string’}.

A role’s attributes can be modified after creation with \texttt{ALTER ROLE}. See the reference pages for the \texttt{CREATE ROLE} and \texttt{ALTER ROLE} commands for details.
Tip: It is good practice to create a role that has the \texttt{CREATEDB} and \texttt{CREATEROLE} privileges, but is not a superuser, and then use this role for all routine management of databases and roles. This approach avoids the dangers of operating as a superuser for tasks that do not really require it.

A role can also have role-specific defaults for many of the run-time configuration settings described in Chapter 18. For example, if for some reason you want to disable index scans (hint: not a good idea) anytime you connect, you can use:

\begin{verbatim}
ALTER ROLE myname SET enable_indexscan TO off;
\end{verbatim}

This will save the setting (but not set it immediately). In subsequent connections by this role it will appear as though \texttt{SET enable_indexscan TO off;} had been executed just before the session started. You can still alter this setting during the session; it will only be the default. To remove a role-specific default setting, use \texttt{ALTER ROLE rolename RESET varname;}. Note that role-specific defaults attached to roles without \texttt{LOGIN} privilege are fairly useless, since they will never be invoked.

### 19.3. Privileges

When an object is created, it is assigned an owner. The owner is normally the role that executed the creation statement. For most kinds of objects, the initial state is that only the owner (or a superuser) can do anything with the object. To allow other roles to use it, \textit{privileges} must be granted. There are several different kinds of privilege: \texttt{SELECT}, \texttt{INSERT}, \texttt{UPDATE}, \texttt{DELETE}, \texttt{REFERENCES}, \texttt{TRIGGER}, \texttt{CREATE}, \texttt{CONNECT}, \texttt{TEMPORARY}, \texttt{EXECUTE}, and \texttt{USAGE}. For more information on the different types of privileges supported by PostgreSQL, see the \texttt{GRANT} reference page.

To assign privileges, the \texttt{GRANT} command is used. So, if \texttt{joe} is an existing role, and \texttt{accounts} is an existing table, the privilege to update the table can be granted with:

\begin{verbatim}
GRANT UPDATE ON accounts TO joe;
\end{verbatim}

The special name \texttt{PUBLIC} can be used to grant a privilege to every role on the system. Writing \texttt{ALL} in place of a specific privilege specifies that all privileges that apply to the object will be granted.

To revoke a privilege, use the fittingly named \texttt{REVOKE} command:

\begin{verbatim}
REVOKE ALL ON accounts FROM PUBLIC;
\end{verbatim}

The special privileges of an object’s owner (i.e., the right to modify or destroy the object) are always implicit in being the owner, and cannot be granted or revoked. But the owner can choose to revoke his own ordinary privileges, for example to make a table read-only for himself as well as others.

An object can be assigned to a new owner with an \texttt{ALTER} command of the appropriate kind for the object. Superusers can always do this; ordinary roles can only do it if they are both the current owner of the object (or a member of the owning role) and a member of the new owning role.

### 19.4. Role Membership

It is frequently convenient to group users together to ease management of privileges: that way, privileges can be granted to, or revoked from, a group as a whole. In PostgreSQL this is done by creating
a role that represents the group, and then granting membership in the group role to individual user roles.

To set up a group role, first create the role:

```
CREATE ROLE name;
```

Typically a role being used as a group would not have the LOGIN attribute, though you can set it if you wish.

Once the group role exists, you can add and remove members using the GRANT and REVOKE commands:

```
GRANT group_role TO role1, ... ;
REVOKE group_role FROM role1, ... ;
```

You can grant membership to other group roles, too (since there isn’t really any distinction between group roles and non-group roles). The database will not let you set up circular membership loops. Also, it is not permitted to grant membership in a role to PUBLIC.

The members of a role can use the privileges of the group role in two ways. First, every member of a group can explicitly do SET ROLE to temporarily “become” the group role. In this state, the database session has access to the privileges of the group role rather than the original login role, and any database objects created are considered owned by the group role not the login role. Second, member roles that have the INHERIT attribute automatically have use of privileges of roles they are members of. As an example, suppose we have done:

```
CREATE ROLE joe LOGIN INHERIT;
CREATE ROLE admin NOINHERIT;
CREATE ROLE wheel NOINHERIT;
GRANT admin TO joe;
GRANT wheel TO admin;
```

Immediately after connecting as role joe, a database session will have use of privileges granted directly to joe plus any privileges granted to admin, because joe “inherits” admin’s privileges. However, privileges granted to wheel are not available, because even though joe is indirectly a member of wheel, the membership is via admin which has the NOINHERIT attribute. After:

```
SET ROLE admin;
```

the session would have use of only those privileges granted to admin, and not those granted to joe. After:

```
SET ROLE wheel;
```

the session would have use of only those privileges granted to wheel, and not those granted to either joe or admin. The original privilege state can be restored with any of:

```
SET ROLE joe;
SET ROLE NONE;
RESET ROLE;
```

Note: The SET ROLE command always allows selecting any role that the original login role is directly or indirectly a member of. Thus, in the above example, it is not necessary to become admin before becoming wheel.
Note: In the SQL standard, there is a clear distinction between users and roles, and users do not automatically inherit privileges while roles do. This behavior can be obtained in PostgreSQL by giving roles being used as SQL roles the INHERIT attribute, while giving roles being used as SQL users the NOINHERIT attribute. However, PostgreSQL defaults to giving all roles the INHERIT attribute, for backwards compatibility with pre-8.1 releases in which users always had use of permissions granted to groups they were members of.

The role attributes LOGIN, SUPERUSER, CREATEDB, and CREATEROLE can be thought of as special privileges, but they are never inherited as ordinary privileges on database objects are. You must actually SET ROLE to a specific role having one of these attributes in order to make use of the attribute. Continuing the above example, we might well choose to grant CREATEDB and CREATEROLE to the admin role. Then a session connecting as role joe would not have these privileges immediately, only after doing SET ROLE admin.

To destroy a group role, use DROP ROLE:

DROP ROLE name;

Any memberships in the group role are automatically revoked (but the member roles are not otherwise affected). Note however that any objects owned by the group role must first be dropped or reassigned to other owners; and any permissions granted to the group role must be revoked.

### 19.5. Functions and Triggers

Functions and triggers allow users to insert code into the backend server that other users might execute unintentionally. Hence, both mechanisms permit users to “Trojan horse” others with relative ease. The only real protection is tight control over who can define functions.

Functions run inside the backend server process with the operating system permissions of the database server daemon. If the programming language used for the function allows unchecked memory accesses, it is possible to change the server’s internal data structures. Hence, among many other things, such functions can circumvent any system access controls. Function languages that allow such access are considered “untrusted”, and PostgreSQL allows only superusers to create functions written in those languages.
Chapter 20. Managing Databases

Every instance of a running PostgreSQL server manages one or more databases. Databases are therefore the topmost hierarchical level for organizing SQL objects ("database objects"). This chapter describes the properties of databases, and how to create, manage, and destroy them.

20.1. Overview

A database is a named collection of SQL objects ("database objects"). Generally, every database object (tables, functions, etc.) belongs to one and only one database. (But there are a few system catalogs, for example `pg_database`, that belong to a whole cluster and are accessible from each database within the cluster.) More accurately, a database is a collection of schemas and the schemas contain the tables, functions, etc. So the full hierarchy is: server, database, schema, table (or some other kind of object, such as a function).

When connecting to the database server, a client must specify in its connection request the name of the database it wants to connect to. It is not possible to access more than one database per connection. (But an application is not restricted in the number of connections it opens to the same or other databases.) Databases are physically separated and access control is managed at the connection level. If one PostgreSQL server instance is to house projects or users that should be separate and for the most part unaware of each other, it is therefore recommendable to put them into separate databases. If the projects or users are interrelated and should be able to use each other's resources they should be put in the same database, but possibly into separate schemas. Schemas are a purely logical structure and who can access what is managed by the privilege system. More information about managing schemas is in Section 5.7.

Databases are created with the `CREATE DATABASE` command (see Section 20.2) and destroyed with the `DROP DATABASE` command (see Section 20.5). To determine the set of existing databases, examine the `pg_database` system catalog, for example

```
SELECT datname FROM pg_database;
```

The psql program's `\l` meta-command and `-l` command-line option are also useful for listing the existing databases.

**Note:** The SQL standard calls databases "catalogs", but there is no difference in practice.

20.2. Creating a Database

In order to create a database, the PostgreSQL server must be up and running (see Section 17.3).

Databases are created with the SQL command `CREATE DATABASE`:

```
CREATE DATABASE name;
```

where `name` follows the usual rules for SQL identifiers. The current role automatically becomes the owner of the new database. It is the privilege of the owner of a database to remove it later on (which also removes all the objects in it, even if they have a different owner).

The creation of databases is a restricted operation. See Section 19.2 for how to grant permission.
Chapter 20. Managing Databases

Since you need to be connected to the database server in order to execute the CREATE DATABASE command, the question remains how the first database at any given site can be created. The first database is always created by the initdb command when the data storage area is initialized. (See Section 17.2.) This database is called postgres. So to create the first “ordinary” database you can connect to postgres.

A second database, template1, is also created by initdb. Whenever a new database is created within the cluster, template1 is essentially cloned. This means that any changes you make in template1 are propagated to all subsequently created databases. Therefore it is unwise to use template1 for real work, but when used judiciously this feature can be convenient. More details appear in Section 20.3.

As a convenience, there is a program that you can execute from the shell to create new databases, createdb.

createdb dbname

createdb does no magic. It connects to the postgres database and issues the CREATE DATABASE command, exactly as described above. The createdb reference page contains the invocation details. Note that createdb without any arguments will create a database with the current user name, which might or might not be what you want.

Note: Chapter 21 contains information about how to restrict who can connect to a given database.

Sometimes you want to create a database for someone else. That role should become the owner of the new database, so he can configure and manage it himself. To achieve that, use one of the following commands:

CREATE DATABASE dbname OWNER rolename;

from the SQL environment, or:

createdb -O rolename dbname

from the shell. You must be a superuser to be allowed to create a database for someone else (that is, for a role you are not a member of).

20.3. Template Databases

CREATE DATABASE actually works by copying an existing database. By default, it copies the standard system database named template1. Thus that database is the “template” from which new databases are made. If you add objects to template1, these objects will be copied into subsequently created user databases. This behavior allows site-local modifications to the standard set of objects in databases. For example, if you install the procedural language PL/pgSQL in template1, it will automatically be available in user databases without any extra action being taken when those databases are made.

There is a second standard system database named template0. This database contains the same data as the initial contents of template1, that is, only the standard objects predefined by your version of PostgreSQL. template0 should never be changed after initdb. By instructing CREATE DATABASE to copy template0 instead of template1, you can create a “virgin” user database that contains none of the site-local additions in template1. This is particularly handy when restoring a pg_dump dump:
the dump script should be restored in a virgin database to ensure that one recreates the correct contents of the dumped database, without any conflicts with additions that can now be present in `template1`.

To create a database by copying `template0`, use:

```
CREATE DATABASE dbname TEMPLATE template0;
```

from the SQL environment, or:

```
createdb -T template0 dbname
```

from the shell.

It is possible to create additional template databases, and indeed one can copy any database in a cluster by specifying its name as the template for `CREATE DATABASE`. It is important to understand, however, that this is not (yet) intended as a general-purpose "COPY DATABASE" facility. The principal limitation is that no other sessions can be connected to the source database while it is being copied. `CREATE DATABASE` will fail if any other connection exists when it starts; otherwise, new connections to the source database are locked out until `CREATE DATABASE` completes.

Two useful flags exist in `pg_database` for each database: the columns `datistemplate` and `datallowconn`. `datistemplate` can be set to indicate that a database is intended as a template for `CREATE DATABASE`. If this flag is set, the database can be cloned by any user with `CREATEDB` privileges; if it is not set, only superusers and the owner of the database can clone it. If `datallowconn` is false, then no new connections to that database will be allowed (but existing sessions are not killed simply by setting the flag false). The `template0` database is normally marked `datallowconn = false` to prevent modification of it. Both `template0` and `template1` should always be marked with `datistemplate = true`.

Note: `template1` and `template0` do not have any special status beyond the fact that the name `template1` is the default source database name for `CREATE DATABASE`. For example, one could drop `template1` and recreate it from `template0` without any ill effects. This course of action might be advisable if one has carelessly added a bunch of junk in `template1`. (To delete `template1`, it must have `pg_database.datistemplate = false`.)

The `postgres` database is also created when a database cluster is initialized. This database is meant as a default database for users and applications to connect to. It is simply a copy of `template1` and can be dropped and recreated if required.

### 20.4. Database Configuration

Recall from Chapter 18 that the PostgreSQL server provides a large number of run-time configuration variables. You can set database-specific default values for many of these settings.

For example, if for some reason you want to disable the GEQO optimizer for a given database, you’d ordinarily have to either disable it for all databases or make sure that every connecting client is careful to issue `SET geqo TO off;`. To make this setting the default within a particular database, you can execute the command:

```
ALTER DATABASE mydb SET geqo TO off;
```

This will save the setting (but not set it immediately). In subsequent connections to this database it will appear as though `SET geqo TO off;` had been executed just before the session started. Note
that users can still alter this setting during their sessions; it will only be the default. To undo any such setting, use \texttt{ALTER DATABASE dbname RESET varname}.

### 20.5. Destroying a Database

Databases are destroyed with the command \texttt{DROP DATABASE}:

\begin{verbatim}
DROP DATABASE name;
\end{verbatim}

Only the owner of the database, or a superuser, can drop a database. Dropping a database removes all objects that were contained within the database. The destruction of a database cannot be undone.

You cannot execute the \texttt{DROP DATABASE} command while connected to the victim database. You can, however, be connected to any other database, including the \texttt{template1} database. \texttt{template1} would be the only option for dropping the last user database of a given cluster.

For convenience, there is also a shell program to drop databases, \texttt{dropdb}:

\begin{verbatim}
dropdb dbname
\end{verbatim}

(Unlike \texttt{createdb}, it is not the default action to drop the database with the current user name.)

### 20.6. Tablespaces

Tablespaces in PostgreSQL allow database administrators to define locations in the file system where the files representing database objects can be stored. Once created, a tablespace can be referred to by name when creating database objects.

By using tablespaces, an administrator can control the disk layout of a PostgreSQL installation. This is useful in at least two ways. First, if the partition or volume on which the cluster was initialized runs out of space and cannot be extended, a tablespace can be created on a different partition and used until the system can be reconfigured.

Second, tablespaces allow an administrator to use knowledge of the usage pattern of database objects to optimize performance. For example, an index which is very heavily used can be placed on a very fast, highly available disk, such as an expensive solid state device. At the same time a table storing archived data which is rarely used or not performance critical could be stored on a less expensive, slower disk system.

To define a tablespace, use the \texttt{CREATE TABLESPACE} command, for example:

\begin{verbatim}
CREATE TABLESPACE fastspace LOCATION '/mnt/sda1/postgresql/data';
\end{verbatim}

The location must be an existing, empty directory that is owned by the PostgreSQL system user. All objects subsequently created within the tablespace will be stored in files underneath this directory.

\textbf{Note:} There is usually not much point in making more than one tablespace per logical file system, since you cannot control the location of individual files within a logical file system. However, PostgreSQL does not enforce any such limitation, and indeed it is not directly aware of the file system boundaries on your system. It just stores files in the directories you tell it to use.
Creation of the tablespace itself must be done as a database superuser, but after that you can allow ordinary database users to make use of it. To do that, grant them the `CREATE` privilege on it.

Tables, indexes, and entire databases can be assigned to particular tablespaces. To do so, a user with the `CREATE` privilege on a given tablespace must pass the tablespace name as a parameter to the relevant command. For example, the following creates a table in the tablespace `space1`:

```
CREATE TABLE foo(i int) TABLESPACE space1;
```

Alternatively, use the `default_tablespace` parameter:

```
SET default_tablespace = space1;
CREATE TABLE foo(i int);
```

When `default_tablespace` is set to anything but an empty string, it supplies an implicit `TABLESPACE` clause for `CREATE TABLE` and `CREATE INDEX` commands that do not have an explicit one.

There is also a `temp_tablespaces` parameter, which determines the placement of temporary tables and indexes, as well as temporary files that are used for purposes such as sorting large data sets. This can be a list of tablespace names, rather than only one, so that the load associated with temporary objects can be spread over multiple tablespaces. A random member of the list is picked each time a temporary object is to be created.

The tablespace associated with a database is used to store the system catalogs of that database. Furthermore, it is the default tablespace used for tables, indexes, and temporary files created within the database, if no `TABLESPACE` clause is given and no other selection is specified by `default_tablespace` or `temp_tablespaces` (as appropriate). If a database is created without specifying a tablespace for it, it uses the same tablespace as the template database it is copied from.

Two tablespaces are automatically created by `initdb`. The `pg_global` tablespace is used for shared system catalogs. The `pg_default` tablespace is the default tablespace of the `template1` and `template0` databases (and, therefore, will be the default tablespace for other databases as well, unless overridden by a `TABLESPACE` clause in `CREATE DATABASE`).

Once created, a tablespace can be used from any database, provided the requesting user has sufficient privilege. This means that a tablespace cannot be dropped until all objects in all databases using the tablespace have been removed.

To remove an empty tablespace, use the `DROP TABLESPACE` command.

To determine the set of existing tablespaces, examine the `pg_tablespace` system catalog, for example

```
SELECT spcname FROM pg_tablespace;
```

The psql program’s `\db` meta-command is also useful for listing the existing tablespaces.

PostgreSQL makes use of symbolic links to simplify the implementation of tablespaces. This means that tablespaces can be used only on systems that support symbolic links.

The directory `$PGDATA/pg_tblspc` contains symbolic links that point to each of the non-built-in tablespaces defined in the cluster. Although not recommended, it is possible to adjust the tablespace layout by hand by redefining these links. Two warnings: do not do so while the server is running; and after you restart the server, update the `pg_tablespace` catalog to show the new locations. (If you do not, `pg_dump` will continue to show the old tablespace locations.)
Chapter 21. Client Authentication

When a client application connects to the database server, it specifies which PostgreSQL database user name it wants to connect as, much the same way one logs into a Unix computer as a particular user. Within the SQL environment the active database user name determines access privileges to database objects — see Chapter 19 for more information. Therefore, it is essential to restrict which database users can connect.

Note: As explained in Chapter 19, PostgreSQL actually does privilege management in terms of “roles”. In this chapter, we consistently use database user to mean “role with the LOGIN privilege”.

Authentication is the process by which the database server establishes the identity of the client, and by extension determines whether the client application (or the user who runs the client application) is permitted to connect with the database user name that was requested.

PostgreSQL offers a number of different client authentication methods. The method used to authenticate a particular client connection can be selected on the basis of (client) host address, database, and user.

PostgreSQL database user names are logically separate from user names of the operating system in which the server runs. If all the users of a particular server also have accounts on the server’s machine, it makes sense to assign database user names that match their operating system user names. However, a server that accepts remote connections might have many database users who have no local operating system account, and in such cases there need be no connection between database user names and OS user names.

21.1. The pg_hba.conf file

Client authentication is controlled by a configuration file, which traditionally is named pg_hba.conf and is stored in the database cluster’s data directory. (HBA stands for host-based authentication.) A default pg_hba.conf file is installed when the data directory is initialized by initdb. It is possible to place the authentication configuration file elsewhere, however; see the hba_file configuration parameter.

The general format of the pg_hba.conf file is a set of records, one per line. Blank lines are ignored, as is any text after the # comment character. A record is made up of a number of fields which are separated by spaces and/or tabs. Fields can contain white space if the field value is quoted. Records cannot be continued across lines.

Each record specifies a connection type, a client IP address range (if relevant for the connection type), a database name, a user name, and the authentication method to be used for connections matching these parameters. The first record with a matching connection type, client address, requested database, and user name is used to perform authentication. There is no “fall-through” or “backup”: if one record is chosen and the authentication fails, subsequent records are not considered. If no record matches, access is denied.

A record can have one of the seven formats

- local
database user auth-method [auth-option]
- host
database user CIDR-address auth-method [auth-option]
- hostssl
database user CIDR-address auth-method [auth-option]
- hostnossl
database user CIDR-address auth-method [auth-option]
Chapter 21. Client Authentication

The meaning of the fields is as follows:

**host**

This record matches connection attempts using Unix-domain sockets. Without a record of this type, Unix-domain socket connections are disallowed.

**hostssl**

This record matches connection attempts made using TCP/IP. *host* records match either SSL or non-SSL connection attempts.

Note: Remote TCP/IP connections will not be possible unless the server is started with an appropriate value for the `listen_addresses` configuration parameter, since the default behavior is to listen for TCP/IP connections only on the local loopback address `localhost`.

**hostnossl**

This record type has the opposite logic to *hostssl*: it only matches connection attempts made over TCP/IP that do not use SSL.

**database**

Specifies which database names this record matches. The value *all* specifies that it matches all databases. The value *sameuser* specifies that the record matches if the requested database has the same name as the requested user. The value *samerole* specifies that the requested user must be a member of the role with the same name as the requested database. (*samegroup* is an obsolete but still accepted spelling of *samerole*.) Otherwise, this is the name of a specific PostgreSQL database. Multiple database names can be supplied by separating them with commas. A separate file containing database names can be specified by preceding the file name with `@`.

**user**

Specifies which database user names this record matches. The value *all* specifies that it matches all users. Otherwise, this is either the name of a specific database user, or a group name preceded by `+`. (Recall that there is no real distinction between users and groups in PostgreSQL; a `+` mark really means “match any of the roles that are directly or indirectly members of this role”, while a name without a `+` mark matches only that specific role.) Multiple user names can be supplied by separating them with commas. A separate file containing user names can be specified by preceding the file name with `@`.

**CIDR-address**

Specifies the client machine IP address range that this record matches. It contains an IP address in standard dotted decimal notation and a CIDR mask length. (IP addresses can only be specified
Chapter 21. Client Authentication

numerically, not as domain or host names.) The mask length indicates the number of high-order bits of the client IP address that must match. Bits to the right of this must be zero in the given IP address. There must not be any white space between the IP address, the /, and the CIDR mask length.

Typical examples of a CIDR-address are 172.20.143.89/32 for a single host, or 172.20.143.0/24 for a small network, or 10.6.0.0/16 for a larger one. To specify a single host, use a CIDR mask of 32 for IPv4 or 128 for IPv6. In a network address, do not omit trailing zeroes.

An IP address given in IPv4 format will match IPv6 connections that have the corresponding address, for example 127.0.0.1 will match the IPv6 address ::ffff:127.0.0.1. An entry given in IPv6 format will match only IPv6 connections, even if the represented address is in the IPv4-in-IPv6 range. Note that entries in IPv6 format will be rejected if the system’s C library does not have support for IPv6 addresses.

This field only applies to host, hostssl, and hostnossl records.

IP-address

IP-mask

These fields can be used as an alternative to the CIDR-address notation. Instead of specifying the mask length, the actual mask is specified in a separate column. For example, 255.0.0.0 represents an IPv4 CIDR mask length of 8, and 255.255.255.255 represents a CIDR mask length of 32.

These fields only apply to host, hostssl, and hostnossl records.

auth-method

Specifies the authentication method to use when connecting via this record. The possible choices are summarized here; details are in Section 21.2.

trust

Allow the connection unconditionally. This method allows anyone that can connect to the PostgreSQL database server to login as any PostgreSQL user they like, without the need for a password. See Section 21.2.1 for details.

reject

Reject the connection unconditionally. This is useful for “filtering out” certain hosts from a group.

md5

Require the client to supply an MD5-encrypted password for authentication. See Section 21.2.2 for details.

crypt

Note: This option is recommended only for communicating with pre-7.2 clients.

Require the client to supply a crypt()-encrypted password for authentication. md5 is now recommended over crypt. See Section 21.2.2 for details.
password

Require the client to supply an unencrypted password for authentication. Since the password is sent in clear text over the network, this should not be used on untrusted networks. It also does not usually work with threaded client applications. See Section 21.2.2 for details.

gss

Use GSSAPI to authenticate the user. This is only available for TCP/IP connections. See Section 21.2.3 for details.

sspi

Use SSPI to authenticate the user. This is only available on Windows. See Section 21.2.4 for details.

krb5

Use Kerberos V5 to authenticate the user. This is only available for TCP/IP connections. See Section 21.2.5 for details.

ident

Obtain the operating system user name of the client (for TCP/IP connections by contacting the ident server on the client, for local connections by getting it from the operating system) and check if the user is allowed to connect as the requested database user by consulting the map specified after the `ident` key word. See Section 21.2.6 for details.

ldap

Authenticate using LDAP to a central server. See Section 21.2.7 for details.

pam

Authenticate using the Pluggable Authentication Modules (PAM) service provided by the operating system. See Section 21.2.8 for details.

auth-option

The meaning of this optional field depends on the chosen authentication method. Details appear below.

Files included by `@` constructs are read as lists of names, which can be separated by either whitespace or commas. Comments are introduced by `#`, just as in `pg_hba.conf`, and nested `@` constructs are allowed. Unless the file name following `@` is an absolute path, it is taken to be relative to the directory containing the referencing file.

Since the `pg_hba.conf` records are examined sequentially for each connection attempt, the order of the records is significant. Typically, earlier records will have tight connection match parameters and weaker authentication methods, while later records will have looser match parameters and stronger authentication methods. For example, one might wish to use `trust` authentication for local TCP/IP connections but require a password for remote TCP/IP connections. In this case a record specifying `trust` authentication for connections from 127.0.0.1 would appear before a record specifying password authentication for a wider range of allowed client IP addresses.

The `pg_hba.conf` file is read on start-up and when the main server process receives a SIGHUP signal. If you edit the file on an active system, you will need to signal the server (using `pg_ctl reload` or `kill -HUP`) to make it re-read the file.
Tip: To connect to a particular database, a user must not only pass the `pg_hba.conf` checks, but must have the `CONNECT` privilege for the database. If you wish to restrict which users can connect to which databases, it's usually easier to control this by granting/revoking `CONNECT` privilege than to put the rules into `pg_hba.conf` entries.

Some examples of `pg_hba.conf` entries are shown in Example 21-1. See the next section for details on the different authentication methods.

**Example 21-1. Example `pg_hba.conf` entries**

```plaintext
# Allow any user on the local system to connect to any database under
# any database user name using Unix-domain sockets (the default for local
# connections).
#
# TYPE    DATABASE    USER    CIDR-ADDRESS    METHOD
local    all         all      all            trust
#
# The same using local loopback TCP/IP connections.
#
# TYPE    DATABASE    USER    CIDR-ADDRESS    METHOD
host     all         all      127.0.0.1/32    trust
#
# The same as the last line but using a separate netmask column
#
# TYPE    DATABASE    USER    IP-ADDRESS    IP-MASK    METHOD
host     all         all      127.0.0.1       255.255.255.255 trust
#
# Allow any user from any host with IP address 192.168.93.x to connect
to database "postgres" as the same user name that ident reports for
# the connection (typically the Unix user name).
#
# TYPE    DATABASE    USER    CIDR-ADDRESS    METHOD
host     postgres    all      192.168.93.0/24 ident sameuser
#
# Allow a user from host 192.168.12.10 to connect to database
# "postgres" if the user's password is correctly supplied.
#
# TYPE    DATABASE    USER    CIDR-ADDRESS    METHOD
host     postgres    all      192.168.12.10/32 md5
#
# In the absence of preceding "host" lines, these two lines will
# reject all connection from 192.168.54.1 (since that entry will be
# matched first), but allow Kerberos 5 connections from anywhere else
# on the Internet. The zero mask means that no bits of the host IP
# address are considered so it matches any host.
#
# TYPE    DATABASE    USER    CIDR-ADDRESS    METHOD
host     all         all      192.168.54.1/32 reject
host     all         all      0.0.0.0/0      krb5
#
# Allow users from 192.168.x.x hosts to connect to any database, if
# they pass the ident check. If, for example, ident says the user is
# "bryanh" and he requests to connect as PostgreSQL user "guest1", the
# connection is allowed if there is an entry in `pg_ident.conf` for map
# "omicron" that says "bryanh" is allowed to connect as "guest1".
```
Chapter 21. Client Authentication

### 21.2. Authentication methods

The following subsections describe the authentication methods in more detail.

#### 21.2.1. Trust authentication

When trust authentication is specified, PostgreSQL assumes that anyone who can connect to the server is authorized to access the database with whatever database user name they specify (including superusers). Of course, restrictions made in the database and user columns still apply. This method should only be used when there is adequate operating-system-level protection on connections to the server.

Trust authentication is appropriate and very convenient for local connections on a single-user workstation. It is usually not appropriate by itself on a multiuser machine. However, you might be able to use trust even on a multiuser machine, if you restrict access to the server’s Unix-domain socket file using file-system permissions. To do this, set the `unix_socket_permissions` (and possibly `unix_socket_group`) configuration parameters as described in Section 18.3. Or you could set the `unix_socket_directory` configuration parameter to place the socket file in a suitably restricted directory.

Setting file-system permissions only helps for Unix-socket connections. Local TCP/IP connections are not restricted by it; therefore, if you want to use file-system permissions for local security, remove the host ... 127.0.0.1 ... line from `pg_hba.conf`, or change it to a non-trust authentication method.

Trust authentication is only suitable for TCP/IP connections if you trust every user on every machine that is allowed to connect to the server by the `pg_hba.conf` lines that specify trust. It is seldom reasonable to use trust for any TCP/IP connections other than those from localhost (127.0.0.1).
21.2.2. Password authentication

The password-based authentication methods are `md5`, `crypt`, and `password`. These methods operate similarly except for the way that the password is sent across the connection: respectively, MD5-hashed, crypt-encrypted, and clear-text. A limitation is that the `crypt` method does not work with passwords that have been encrypted in `pg_authid`.

If you are at all concerned about password “sniffing” attacks then `md5` is preferred, with `crypt` to be used only if you must support pre-7.2 clients. Plain `password` should be avoided especially for connections over the open Internet (unless you use SSL, SSH, or another communications security wrapper around the connection).

PostgreSQL database passwords are separate from operating system user passwords. The password for each database user is stored in the `pg_authid` system catalog. Passwords can be managed with the SQL commands `CREATE USER` and `ALTER USER`, e.g., `CREATE USER foo WITH PASSWORD 'secret';`. By default, that is, if no password has been set up, the stored password is null and password authentication will always fail for that user.

21.2.3. GSSAPI authentication

GSSAPI is an industry-standard protocol for secure authentication defined in RFC 2743. PostgreSQL supports GSSAPI with Kerberos authentication according to RFC 1964. GSSAPI provides automatic authentication (single sign-on) for systems that support it. The authentication itself is secure, but the data sent over the connection will be in clear unless SSL is used.

When GSSAPI uses Kerberos, it uses a standard principal in format `servicename/hostname@realm`. For information about the parts of the principal, and how to set up the required keys, see Section 21.2.5. GSSAPI support has to be enabled when PostgreSQL is built; see Chapter 15 for more information.

21.2.4. SSPI authentication

SSPI is a Windows technology for secure authentication with single sign-on. PostgreSQL will use SSPI in `negotiate` mode, which will use Kerberos when possible and automatically fall back to NTLM in other cases. SSPI authentication only works when both server and client are running Windows.

When using Kerberos authentication, SSPI works the same way GSSAPI does. See Section 21.2.3 for details.

21.2.5. Kerberos authentication

Note: Native Kerberos authentication has been deprecated and should be used only for backward compatibility. New and upgraded installations are encouraged to use the industry-standard GSSAPI authentication (see Section 21.2.3) instead.

Kerberos is an industry-standard secure authentication system suitable for distributed computing over a public network. A description of the Kerberos system is far beyond the scope of this document; in
Chapter 21. Client Authentication

full generality it can be quite complex (yet powerful). The Kerberos FAQ¹ or MIT Kerberos page² can be good starting points for exploration. Several sources for Kerberos distributions exist. Kerberos provides secure authentication but does not encrypt queries or data passed over the network; for that use SSL.

PostgreSQL supports Kerberos version 5. Kerberos support has to be enabled when PostgreSQL is built; see Chapter 15 for more information.

PostgreSQL operates like a normal Kerberos service. The name of the service principal is servicename/hostname@realm.

servicename can be set on the server side using the krb_srvname configuration parameter, and on the client side using the krbsrvname connection parameter. (See also Section 30.1.) The installation default can be changed from the default postgres at build time using ./configure --with-krb-srvname=whatever. In most environments, this parameter never needs to be changed. However, to support multiple PostgreSQL installations on the same host it is necessary. Some Kerberos implementations might also require a different service name, such as Microsoft Active Directory which requires the service name to be in uppercase (POSTGRES).

hostname is the fully qualified host name of the server machine. The service principal’s realm is the preferred realm of the server machine.

Client principals must have their PostgreSQL database user name as their first component, for example pgusertextname@realm. By default, the realm of the client is not checked by PostgreSQL. If you have cross-realm authentication enabled and need to verify the realm, use the krb_realm parameter.

Make sure that your server keytab file is readable (and preferably only readable) by the PostgreSQL server account. (See also Section 17.1.) The location of the key file is specified by the krb_server_keyfile configuration parameter. The default is /usr/local/pgsql/etc/krb5.keytab (or whichever directory was specified as sysconfdir at build time).

The keytab file is generated by the Kerberos software; see the Kerberos documentation for details. The following example is for MIT-compatible Kerberos 5 implementations:

```
  kadmin% ank -randkey postgres/server.my.domain.org
  kadmin% ktadd -k krb5.keytab postgres/server.my.domain.org
```

When connecting to the database make sure you have a ticket for a principal matching the requested database user name. For example, for database user name fred, both principal fred@example.com and fred/users.example.com@example.com could be used to authenticate to the database server.

If you use mod_auth_kerb³ and mod_perl on your Apache web server, you can use AuthType KerberosV5SaveCredentials with a mod_perl script. This gives secure database access over the web, no extra passwords required.

### 21.2.6. Ident-based authentication

The ident authentication method works by obtaining the client’s operating system user name, then determining the allowed database user names using a map file that lists the permitted corresponding

---

pairs of names. The determination of the client’s user name is the security-critical point, and it works differently depending on the connection type.

### 21.2.6.1. Ident Authentication over TCP/IP

The “Identification Protocol” is described in RFC 1413. Virtually every Unix-like operating system ships with an ident server that listens on TCP port 113 by default. The basic functionality of an ident server is to answer questions like “What user initiated the connection that goes out of your port \( x \) and connects to my port \( y \)?". Since PostgreSQL knows both \( x \) and \( y \) when a physical connection is established, it can interrogate the ident server on the host of the connecting client and could theoretically determine the operating system user for any given connection this way.

The drawback of this procedure is that it depends on the integrity of the client: if the client machine is untrusted or compromised an attacker could run just about any program on port 113 and return any user name he chooses. This authentication method is therefore only appropriate for closed networks where each client machine is under tight control and where the database and system administrators operate in close contact. In other words, you must trust the machine running the ident server. Heed the warning:

> The Identification Protocol is not intended as an authorization or access control protocol.  
> —RFC 1413

Some ident servers have a nonstandard option that causes the returned user name to be encrypted, using a key that only the originating machine’s administrator knows. This option must not be used when using the ident server with PostgreSQL, since PostgreSQL does not have any way to decrypt the returned string to determine the actual user name.

### 21.2.6.2. Ident Authentication over Local Sockets

On systems supporting `SO_PEERCRED` requests for Unix-domain sockets (currently Linux, FreeBSD, NetBSD, OpenBSD, and BSD/OS), ident authentication can also be applied to local connections. In this case, no security risk is added by using ident authentication; indeed it is a preferable choice for local connections on such systems.

On systems without `SO_PEERCRED` requests, ident authentication is only available for TCP/IP connections. As a work-around, it is possible to specify the localhost address 127.0.0.1 and make connections to this address. This method is trustworthy to the extent that you trust the local ident server.

### 21.2.6.3. Ident Maps

When using ident-based authentication, after having determined the name of the operating system user that initiated the connection, PostgreSQL checks whether that user is allowed to connect as the database user he is requesting to connect as. This is controlled by the ident map argument that follows the `ident` key word in the `pg_hba.conf` file. There is a predefined ident map `sameuser`, which allows any operating system user to connect as the database user of the same name (if the latter exists). Other maps must be created manually.

Ident maps other than `sameuser` are defined in the ident map file, which by default is named `pg_ident.conf` and is stored in the cluster’s data directory. (It is possible to place the map file elsewhere, however; see the `ident_file` configuration parameter.) The ident map file contains lines of the general form:

```
map-name ident-username database-username
```
Comments and whitespace are handled in the same way as in \texttt{pg\_hba.conf}. The map-name is an arbitrary name that will be used to refer to this mapping in \texttt{pg\_hba.conf}. The other two fields specify which operating system user is allowed to connect as which database user. The same map-name can be used repeatedly to specify more user-mappings within a single map. There is no restriction regarding how many database users a given operating system user can correspond to, nor vice versa.

The \texttt{pg\_ident.conf} file is read on start-up and when the main server process receives a SIGHUP signal. If you edit the file on an active system, you will need to signal the server (using \texttt{pg\_ctl reload} or \texttt{kill \ -HUP}) to make it re-read the file.

A \texttt{pg\_ident.conf} file that could be used in conjunction with the \texttt{pg\_hba.conf} file in Example 21-1 is shown in Example 21-2. In this example setup, anyone logged in to a machine on the 192.168 network that does not have the Unix user name \texttt{bryan}, \texttt{ann}, or \texttt{robert} would not be granted access. Unix user \texttt{robert} would only be allowed access when he tries to connect as PostgreSQL user \texttt{bob}, not as \texttt{robert} or anyone else. \texttt{ann} would only be allowed to connect as \texttt{ann}. User \texttt{bryan} would be allowed to connect as either \texttt{bryan} himself or as \texttt{guest1}.

\texttt{Example 21-2. An example pg\_ident.conf file}

\begin{verbatim}
# MAPNAME IDENT-USERNAME PG-USERNAME
omicron bryan bryan
omicron ann ann
# bob has user name robert on these machines
omicron robert bob
# bryan can also connect as guest1
omicron bryan guest1
\end{verbatim}

\subsection{21.2.7. LDAP authentication}

This authentication method operates similarly to \texttt{password} except that it uses LDAP as the authentication method. LDAP is used only to validate the user name/password pairs. Therefore the user must already exist in the database before LDAP can be used for authentication. The server and parameters used are specified after the \texttt{ldap} key word in the file \texttt{pg\_hba.conf}. The format of this parameter is:

\texttt{ldap[s]://servername[:port]/base\:dn[\:prefix[\:suffix]]}

Commas are used to specify multiple items in an \texttt{ldap} component. However, because unquoted commas are treated as item separators in \texttt{pg\_hba.conf}, it is wise to double-quote the \texttt{ldap} URL to preserve any commas present, e.g.:

\texttt{"ldap://ldap.example.net/dc=example,dc=net;EXAMPLE"}

If \texttt{ldaps} is specified instead of \texttt{ldap}, TLS encryption will be enabled for the connection. Note that this will encrypt only the connection between the PostgreSQL server and the LDAP server. The connection between the client and the PostgreSQL server is not affected by this setting. To make use of TLS encryption, you might need to configure the LDAP library prior to configuring PostgreSQL. Note that encrypted LDAP is available only if the platform’s LDAP library supports it.

If no port is specified, the default port as configured in the LDAP library will be used.
Chapter 21. Client Authentication

The server will bind to the distinguished name specified as base dn using the user name supplied by the client. If prefix and suffix is specified, it will be prepended and appended to the user name before the bind. Typically, the prefix parameter is used to specify cn=, or \DOMAIN\ in an Active Directory environment.

21.2.8. PAM authentication

This authentication method operates similarly to password except that it uses PAM (Pluggable Authentication Modules) as the authentication mechanism. The default PAM service name is postgresql. You can optionally supply your own service name after the pam key word in the file pg_hba.conf. PAM is used only to validate user name/password pairs. Therefore the user must already exist in the database before PAM can be used for authentication. For more information about PAM, please read the Linux-PAM Page\(^4\) and the Solaris PAM Page\(^5\).

**Note:** If PAM is set up to read /etc/shadow, authentication will fail because the PostgreSQL server is started by a non-root user. However, this is not an issue with LDAP or other authentication methods.

21.3. Authentication problems

Genuine authentication failures and related problems generally manifest themselves through error messages like the following.

**FATAL:** no pg_hba.conf entry for host "123.123.123.123", user "andym", database "testdb"

This is what you are most likely to get if you succeed in contacting the server, but it does not want to talk to you. As the message suggests, the server refused the connection request because it found no matching entry in its pg_hba.conf configuration file.

**FATAL:** Password authentication failed for user "andym"

Messages like this indicate that you contacted the server, and it is willing to talk to you, but not until you pass the authorization method specified in the pg_hba.conf file. Check the password you are providing, or check your Kerberos or ident software if the complaint mentions one of those authentication types.

**FATAL:** user "andym" does not exist

The indicated user name was not found.

**FATAL:** database "testdb" does not exist

The database you are trying to connect to does not exist. Note that if you do not specify a database name, it defaults to the database user name, which might or might not be the right thing.

\(^4\) http://www.kernel.org/pub/linux/libs/pam/
\(^5\) http://www.sun.com/software/solaris/pam/
Tip: The server log might contain more information about an authentication failure than is reported to the client. If you are confused about the reason for a failure, check the log.
Chapter 22. Localization

This chapter describes the available localization features from the point of view of the administrator. PostgreSQL supports localization with two approaches:

- Using the locale features of the operating system to provide locale-specific collation order, number formatting, translated messages, and other aspects.
- Providing a number of different character sets defined in the PostgreSQL server, including multi-byte character sets, to support storing text in all kinds of languages, and providing character set translation between client and server.

22.1. Locale Support

Locale support refers to an application respecting cultural preferences regarding alphabets, sorting, number formatting, etc. PostgreSQL uses the standard ISO C and POSIX locale facilities provided by the server operating system. For additional information refer to the documentation of your system.

22.1.1. Overview

Locale support is automatically initialized when a database cluster is created using `initdb`. `initdb` will initialize the database cluster with the locale setting of its execution environment by default, so if your system is already set to use the locale that you want in your database cluster then there is nothing else you need to do. If you want to use a different locale (or you are not sure which locale your system is set to), you can instruct `initdb` exactly which locale to use by specifying the `--locale` option. For example:

```
initdb --locale=sv_SE
```

This example sets the locale to Swedish (`sv`) as spoken in Sweden (`SE`). Other possibilities might be `en_US` (U.S. English) and `fr_CA` (French Canadian). If more than one character set can be useful for a locale then the specifications look like this: `cs_CZ.ISO8859-2`. What locales are available under what names on your system depends on what was provided by the operating system vendor and what was installed. (On most systems, the command `locale -a` will provide a list of available locales.)

Occasionally it is useful to mix rules from several locales, e.g., use English collation rules but Spanish messages. To support that, a set of locale subcategories exist that control only a certain aspect of the localization rules:

<table>
<thead>
<tr>
<th>LC_COLLATE</th>
<th>String sort order</th>
</tr>
</thead>
<tbody>
<tr>
<td>LC_CTYPE</td>
<td>Character classification (What is a letter? Its upper-case equivalent?)</td>
</tr>
<tr>
<td>LC_MESSAGES</td>
<td>Language of messages</td>
</tr>
<tr>
<td>LC_MONETARY</td>
<td>Formatting of currency amounts</td>
</tr>
<tr>
<td>LC_NUMERIC</td>
<td>Formatting of numbers</td>
</tr>
</tbody>
</table>
Formatting of dates and times

The category names translate into names of `initdb` options to override the locale choice for a specific category. For instance, to set the locale to French Canadian, but use U.S. rules for formatting currency, use `initdb --locale=fr_CA --lc-monetary=en_US`.

If you want the system to behave as if it had no locale support, use the special locale `C` or `POSIX`.

The nature of some locale categories is that their value has to be fixed for the lifetime of a database cluster. That is, once `initdb` has run, you cannot change them anymore. `LC_COLLATE` and `LC_CTYPE` are those categories. They affect the sort order of indexes, so they must be kept fixed, or indexes on text columns will become corrupt. PostgreSQL enforces this by recording the values of `LC_COLLATE` and `LC_CTYPE` that are seen by `initdb`. The server automatically adopts those two values when it is started.

The other locale categories can be changed as desired whenever the server is running by setting the run-time configuration variables that have the same name as the locale categories (see Section 18.10.2 for details). The defaults that are chosen by `initdb` are actually only written into the configuration file `postgresql.conf` to serve as defaults when the server is started. If you delete these assignments from `postgresql.conf` then the server will inherit the settings from its execution environment.

Note that the locale behavior of the server is determined by the environment variables seen by the server, not by the environment of any client. Therefore, be careful to configure the correct locale settings before starting the server. A consequence of this is that if client and server are set up in different locales, messages might appear in different languages depending on where they originated.

Note: When we speak of inheriting the locale from the execution environment, this means the following on most operating systems: For a given locale category, say the collation, the following environment variables are consulted in this order until one is found to be set: `LC_ALL`, `LC_COLLATE` (the variable corresponding to the respective category), `LANG`. If none of these environment variables are set then the locale defaults to `C`.

Some message localization libraries also look at the environment variable `LANGUAGE` which overrides all other locale settings for the purpose of setting the language of messages. If in doubt, please refer to the documentation of your operating system, in particular the documentation about `gettext`, for more information.

To enable messages to be translated to the user’s preferred language, NLS must have been enabled at build time. This choice is independent of the other locale support.

### 22.1.2. Behavior

The locale settings influence the following SQL features:

- Sort order in queries using `ORDER BY` on textual data
- The ability to use indexes with `LIKE` clauses
- The `upper`, `lower`, and `initcap` functions
- The `to_char` family of functions
The drawback of using locales other than C or POSIX in PostgreSQL is its performance impact. It slows character handling and prevents ordinary indexes from being used by LIKE. For this reason use locales only if you actually need them.

As a workaround to allow PostgreSQL to use indexes with LIKE clauses under a non-C locale, several custom operator classes exist. These allow the creation of an index that performs a strict character-by-character comparison, ignoring locale comparison rules. Refer to Section 11.9 for more information.

### 22.1.3. Problems

If locale support doesn’t work according to the explanation above, check that the locale support in your operating system is correctly configured. To check what locales are installed on your system, you can use the command `locale -a` if your operating system provides it.

Check that PostgreSQL is actually using the locale that you think it is. **LC_COLLATE** and **LC_CTYPE** settings are determined at initdb time and cannot be changed without repeating initdb. Other locale settings including **LC_MESSAGES** and **LC_MONETARY** are initially determined by the environment the server is started in, but can be changed on-the-fly. You can check the active locale settings using the `SHOW` command.

The directory `src/test/locale` in the source distribution contains a test suite for PostgreSQL’s locale support.

Client applications that handle server-side errors by parsing the text of the error message will obviously have problems when the server’s messages are in a different language. Authors of such applications are advised to make use of the error code scheme instead.

Maintaining catalogs of message translations requires the on-going efforts of many volunteers that want to see PostgreSQL speak their preferred language well. If messages in your language are currently not available or not fully translated, your assistance would be appreciated. If you want to help, refer to Chapter 47 or write to the developers’ mailing list.

### 22.2. Character Set Support

The character set support in PostgreSQL allows you to store text in a variety of character sets (also called encodings), including single-byte character sets such as the ISO 8859 series and multiple-byte character sets such as EUC (Extended Unix Code), UTF-8, and Mule internal code. All supported character sets can be used transparently by clients, but a few are not supported for use within the server (that is, as a server-side encoding). The default character set is selected while initializing your PostgreSQL database cluster using initdb. It can be overridden when you create a database, so you can have multiple databases each with a different character set.

An important restriction, however, is that each database character set must be compatible with the server’s **LC_CTYPE** setting. When **LC_CTYPE** is C or POSIX, any character set is allowed, but for other settings of **LC_CTYPE** there is only one character set that will work correctly. Since the **LC_CTYPE** setting is frozen by initdb, the apparent flexibility to use different encodings in different databases of a cluster is more theoretical than real, except when you select C or POSIX locale (thus disabling any real locale awareness). It is likely that these mechanisms will be revisited in future versions of PostgreSQL.
# 22.2.1. Supported Character Sets

Table 22-1 shows the character sets available for use in PostgreSQL.

</tbody>
</table>

Not all APIs support all the listed character sets. For example, the PostgreSQL JDBC driver does not support MULE_INTERNAL, LATIN6, LATIN8, and LATIN10.

The SQL_ASCII setting behaves considerably differently from the other settings. When the server character set is SQL_ASCII, the server interprets byte values 0-127 according to the ASCII standard, while byte values 128-255 are taken as uninterpreted characters. No encoding conversion will be done when the setting is SQL_ASCII. Thus, this setting is not so much a declaration that a specific encoding is in use, as a declaration of ignorance about the encoding. In most cases, if you are working with any non-ASCII data, it is unwise to use the SQL_ASCII setting, because PostgreSQL will be unable to help you by converting or validating non-ASCII characters.

22.2.2. Setting the Character Set

initdb defines the default character set for a PostgreSQL cluster. For example,

```bash
initdb -E EUC_JP
```

sets the default character set (encoding) to EUC_JP (Extended Unix Code for Japanese). You can use --encoding instead of -E if you prefer to type longer option strings. If no -E or --encoding option is given, initdb attempts to determine the appropriate encoding to use based on the specified or default locale.

If you have selected C or POSIX locale, you can create a database with a different character set:

```bash
createdb -E EUC_KR korean
```

This will create a database named korean that uses the character set EUC_KR. Another way to accomplish this is to use this SQL command:

```sql
CREATE DATABASE korean WITH ENCODING 'EUC_KR';
```

The encoding for a database is stored in the system catalog pg_database. You can see it by using the \l option or the \l command of psql.

```bash
$ psql -l
```

</table>

415
Important: On most modern operating systems, PostgreSQL can determine which character set is implied by an `LC_CTYPE` setting, and it will enforce that only the correct database encoding is used. On older systems it is your responsibility to ensure that you use the encoding expected by the locale you have selected. A mistake in this area is likely to lead to strange misbehavior of locale-dependent operations such as sorting.

PostgreSQL will allow superusers to create databases with `SQL_ASCII` encoding even when `LC_CTYPE` is not `C` or `POSIX`. As noted above, `SQL_ASCII` does not enforce that the data stored in the database has any particular encoding, and so this choice poses risks of locale-dependent misbehavior. Using this combination of settings is deprecated and may someday be forbidden altogether.

### 22.2.3. Automatic Character Set Conversion Between Server and Client

PostgreSQL supports automatic character set conversion between server and client for certain character set combinations. The conversion information is stored in the `pg_conversion` system catalog. PostgreSQL comes with some predefined conversions, as shown in Table 22-2. You can create a new conversion using the SQL command `CREATE CONVERSION`.

<table>

</tbody>
</table>

To enable automatic character set conversion, you have to tell PostgreSQL the character set (encoding) you would like to use in the client. There are several ways to accomplish this:

- **Using the \encoding command in psql.** \encoding allows you to change client encoding on the fly. For example, to change the encoding to SJIS, type:

  \encoding SJIS

- **libpq (Section 30.9) has functions to control the client encoding.**

- **Using SET client_encoding TO.** Setting the client encoding can be done with this SQL command:

  ```sql
  SET CLIENT_ENCODING TO 'value';
  ``

  Also you can use the standard SQL syntax SET NAMES for this purpose:

  ```sql
  SET NAMES 'value';
  ``

  To query the current client encoding:

  ```sql
  SHOW client_encoding;
  ``

  To return to the default encoding:
RESET client_encoding;

- **Using PGCLIENTENCODING.** If the environment variable `PGCLIENTENCODING` is defined in the client’s environment, that client encoding is automatically selected when a connection to the server is made. (This can subsequently be overridden using any of the other methods mentioned above.)

- **Using the configuration variable client_encoding.** If the `client_encoding` variable is set, that client encoding is automatically selected when a connection to the server is made. (This can subsequently be overridden using any of the other methods mentioned above.)

If the conversion of a particular character is not possible — suppose you chose `EUC_JP` for the server and `LATIN1` for the client, then some Japanese characters do not have a representation in `LATIN1` — then an error is reported.

If the client character set is defined as `SQL_ASCII`, encoding conversion is disabled, regardless of the server’s character set. Just as for the server, use of `SQL_ASCII` is unwise unless you are working with all-ASCII data.

Chapter 23. Routine Database Maintenance Tasks

PostgreSQL, like any database software, requires that certain tasks be performed regularly to achieve optimum performance. The tasks discussed here are required, but they are repetitive in nature and can easily be automated using standard Unix tools such as cron scripts or Windows’ Task Scheduler. But it is the database administrator’s responsibility to set up appropriate scripts, and to check that they execute successfully.

One obvious maintenance task is creation of backup copies of the data on a regular schedule. Without a recent backup, you have no chance of recovery after a catastrophe (disk failure, fire, mistakenly dropping a critical table, etc.). The backup and recovery mechanisms available in PostgreSQL are discussed at length in Chapter 24.

The other main category of maintenance task is periodic “vacuuming” of the database. This activity is discussed in Section 23.1. Closely related to this is updating the statistics that will be used by the query planner, as discussed in Section 23.1.2.

Another task that might need periodic attention is log file management. This is discussed in Section 23.3.

PostgreSQL is low-maintenance compared to some other database management systems. Nonetheless, appropriate attention to these tasks will go far towards ensuring a pleasant and productive experience with the system.

23.1. Routine Vacuuming

PostgreSQL’s VACUUM command has to run on a regular basis for several reasons:

1. To recover or reuse disk space occupied by updated or deleted rows.
2. To update data statistics used by the PostgreSQL query planner.
3. To protect against loss of very old data due to transaction ID wraparound.

The standard form of VACUUM can run in parallel with production database operations. Commands such as SELECT, INSERT, UPDATE, and DELETE will continue to function as normal, though you will not be able to modify the definition of a table with commands such as ALTER TABLE ADD COLUMN while it is being vacuumed. Also, VACUUM requires a substantial amount of I/O traffic, which can cause poor performance for other active sessions. There are configuration parameters that can be adjusted to reduce the performance impact of background vacuuming — see Section 18.4.4.

Fortunately, The Auto-Vacuum Daemon monitors table activity and performs VACUUMs when necessary. Autovacuum works dynamically so it is often better administration-scheduled vacuuming.

23.1.1. Recovering Disk Space

In normal PostgreSQL operation, an UPDATE or DELETE of a row does not immediately remove the old version of the row. This approach is necessary to gain the benefits of multiversion concurrency control (see Chapter 13): the row versions must not be deleted while it is still potentially visible to other transactions. But eventually, an outdated or deleted row version is no longer of interest to any
transaction. The space it occupies must be reclaimed for reuse by new rows, to avoid infinite growth of disk space requirements. This is done by running \texttt{VACUUM}.

There are two variants of the \texttt{VACUUM} command. The first form, known as “lazy vacuum” or just \texttt{VACUUM}, marks dead data in tables and indexes for future reuse; it does \textit{not} attempt to reclaim the space used by this dead data unless the space is at the end of the table and an exclusive table lock can be easily obtained. Unused space at the start or middle of the file does not result in the file being shortened and space returned to the operating system. This variant of \texttt{VACUUM} can be run concurrently with normal database operations.

The second form is the \texttt{VACUUM FULL} command. This uses a more aggressive algorithm for reclaiming the space consumed by dead row versions. Any space that is freed by \texttt{VACUUM FULL} is immediately returned to the operating system, and the table data is physically compacted on the disk. Unfortunately, this variant of the \texttt{VACUUM} command acquires an exclusive lock on each table while \texttt{VACUUM FULL} is processing it. Therefore, frequently using \texttt{VACUUM FULL} can have an extremely negative effect on the performance of concurrent database queries.

Fortunately, \textit{The Auto-Vacuum Daemon} monitors table activity and performs \texttt{VACUUM}s when necessary. This eliminates the need for administrators to worry about disk space recovery in all but the most unusual cases.

For administrators who want to control \texttt{VACUUM} themselves, the standard form of \texttt{VACUUM} is best used to maintain a steady-state usage of disk space. If you need to return disk space to the operating system, you can use \texttt{VACUUM FULL}, but this is unwise if the table will just grow again in the future. Moderately-frequent standard \texttt{VACUUM} runs are a better approach than infrequent \texttt{VACUUM FULL} runs for maintaining heavily-updated tables. However, if some heavily-updated tables have gone too long with infrequent \texttt{VACUUM}, you can use \texttt{VACUUM FULL} or \texttt{CLUSTER} to get performance back (it is much slower to scan a table containing almost only dead rows).

For those not using autovacuum, one approach is to schedule a database-wide \texttt{VACUUM} once a day during low-usage period, supplemented by more frequent vacuuming of heavily-updated tables if necessary. (Some installations with extremely high update rates vacuum their busiest tables as often as once every few minutes.) If you have multiple databases in a cluster, don’t forget to \texttt{VACUUM} each one; the program \texttt{vacuumdb} might be helpful.

\texttt{VACUUM FULL} is recommended for cases where you know you have deleted the majority of rows in a table, so that the steady-state size of the table can be shrunk substantially with \texttt{VACUUM FULL}’s more aggressive approach. Use plain \texttt{VACUUM}, not \texttt{VACUUM FULL}, for routine vacuuming for space recovery.

If you have a table whose entire contents are deleted on a periodic basis, consider doing it with \texttt{TRUNCATE} rather than using \texttt{DELETE} followed by \texttt{VACUUM}. \texttt{TRUNCATE} removes the entire content of the table immediately, without requiring a subsequent \texttt{VACUUM} or \texttt{VACUUM FULL} to reclaim the now-unused disk space.

\subsection*{23.1.2. Updating Planner Statistics}

The PostgreSQL query planner relies on statistical information about the contents of tables in order to generate good plans for queries. These statistics are gathered by the \texttt{ANALYZE} command, which can be invoked by itself or as an optional step in \texttt{VACUUM}. It is important to have reasonably accurate statistics, otherwise poor choices of plans might degrade database performance.

As with vacuuming for space recovery, frequent updates of statistics are more useful for heavily-updated tables than for seldom-updated ones. But even for a heavily-updated table, there might be no need for statistics updates if the statistical distribution of the data is not changing much. A simple rule of thumb is to think about how much the minimum and maximum values of the columns in the
Chapter 23. Routine Database Maintenance Tasks

table change. For example, a timestamp column that contains the time of row update will have a constantly-increasing maximum value as rows are added and updated; such a column will probably need more frequent statistics updates than, say, a column containing URLs for pages accessed on a website. The URL column might receive changes just as often, but the statistical distribution of its values probably changes relatively slowly.

It is possible to run `ANALYZE` on specific tables and even just specific columns of a table, so the flexibility exists to update some statistics more frequently than others if your application requires it. In practice, however, it is usually best to just analyze the entire database because it is a fast operation. It uses a statistical random sampling of the rows of a table rather than reading every single row.

**Tip:** Although per-column tweaking of `ANALYZE` frequency might not be very productive, you might well find it worthwhile to do per-column adjustment of the level of detail of the statistics collected by `ANALYZE`. Columns that are heavily used in `WHERE` clauses and have highly irregular data distributions might require a finer-grain data histogram than other columns. See `ALTER TABLE SET STATISTICS`.

Fortunately, *The Auto-Vacuum Daemon* monitors table activity and performs `ANALYZE` when necessary. This eliminates the need for administrators to manually schedule `ANALYZE`.

For those not using autovacuum, one approach is to schedule a database-wide `ANALYZE` once a day at a low-usage time of day; this can usefully be combined with a nightly `VACUUM`. However, sites with relatively slowly changing table statistics might find that this is overkill, and that less-frequent `ANALYZE` runs are sufficient.

### 23.1.3. Preventing Transaction ID Wraparound Failures

PostgreSQL’s MVCC transaction semantics depend on being able to compare transaction ID (XID) numbers: a row version with an insertion XID greater than the current transaction’s XID is “in the future” and should not be visible to the current transaction. But since transaction IDs have limited size (32 bits at this writing) a cluster that runs for a long time (more than 4 billion transactions) would suffer transaction ID wraparound: the XID counter wraps around to zero, and all of a sudden transactions that were in the past appear to be in the future — which means their outputs become invisible. In short, catastrophic data loss. (Actually the data is still there, but that’s cold comfort if you cannot get at it.) To avoid this, it is necessary to vacuum every table in every database at least once every two billion transactions.

The reason that periodic vacuuming solves the problem is that PostgreSQL distinguishes a special XID FrozenXID. This XID is always considered older than every normal XID. Normal XIDs are compared using modulo-$2^{31}$ arithmetic. This means that for every normal XID, there are two billion XIDs that are “older” and two billion that are “newer”; another way to say it is that the normal XID space is circular with no endpoint. Therefore, once a row version has been created with a particular normal XID, the row version will appear to be “in the past” for the next two billion transactions, no matter which normal XID we are talking about. If the row version still exists after more than two billion transactions, it will suddenly appear to be in the future. To prevent data loss, old row versions must be reassigned the XID FrozenXID sometime before they reach the two-billion-transactions-old mark. Once they are assigned this special XID, they will appear to be “in the past” to all normal transactions regardless of wraparound issues, and so such row versions will be good until deleted, no matter how long that is. This reassignment of old XIDs is handled by `VACUUM`.

`VACUUM`'s behavior is controlled by the configuration parameter `vacuum_freeze_min_age`: any XID older than `vacuum_freeze_min_age` transactions is replaced by FrozenXID. Larger values of
Chapter 23. Routine Database Maintenance Tasks

vacuum_freeze_min_age preserves transactional information longer, while smaller values increase the number of transactions that can elapse before the table must be vacuumed again.

The maximum time that a table can go unvacuumed is two billion transactions minus the vacuum_freeze_min_age that was used when it was last vacuumed. If it were to go unvacuumed for longer than that, data loss could result. To ensure that this does not happen, the Auto-Vacuum Daemon is invoked on any table that might contain XIDs older than the age specified by the configuration parameter autovacuum_freeze_max_age. (This will happen even if autovacuum is otherwise disabled.)

This implies that if a table is not otherwise vacuumed, autovacuum will be invoked on it approximately once every autovacuum_freeze_max_age minus vacuum_freeze_min_age transactions. For tables that are regularly vacuumed for space reclamation purposes, this is of little importance. However, for static tables (including tables that receive inserts, but no updates or deletes), there is no need for vacuuming for space reclamation, and so it can be useful to try to maximize the interval between forced autovacuums on very large static tables. Obviously one can do this either by increasing autovacuum_freeze_max_age or by decreasing vacuum_freeze_min_age.

The sole disadvantage of increasing autovacuum_freeze_max_age is that the pg_clog subdirectory of the database cluster will take more space, because it must store the commit status for all transactions back to the autovacuum_freeze_max_age horizon. The commit status uses two bits per transaction, so if autovacuum_freeze_max_age has its maximum allowed value of two billion, pg_clog can be expected to grow to about half a gigabyte. If this is trivial compared to your total database size, setting autovacuum_freeze_max_age to its maximum allowed value is recommended. Otherwise, set it depending on what you are willing to allow for pg_clog storage. (The default, 200 million transactions, translates to about 50MB of pg_clog storage.)

One disadvantage of decreasing vacuum_freeze_min_age is that it might cause VACUUM to do useless work: changing a table row’s XID to FrozenXID is a waste of time if the row is modified soon thereafter (causing it to acquire a new XID). So the setting should be large enough that rows are not frozen until they are unlikely to change any more. Another disadvantage of decreasing this setting is that details about exactly which transaction inserted or modified a row will be lost sooner. This information sometimes comes in handy, particularly when trying to analyze what went wrong after a database failure. For these two reasons, decreasing this setting is not recommended except for completely static tables.

To track the age of the oldest XIDs in a database, VACUUM stores XID statistics in the system tables pg_class and pg_database. In particular, the relfrozenxid column of a table’s pg_class row contains the freeze cutoff XID that was used by the last VACUUM for that table. All normal XIDs older than this cutoff XID are guaranteed to have been replaced by FrozenXID within the table. Similarly, the datfrozenxid column of a database’s pg_database row is a lower bound on the normal XIDs appearing in that database — it is just the minimum of the per-table relfrozenxid values within the database. A convenient way to examine this information is to execute queries such as:

```sql
SELECT relname, age(relfrozenxid) FROM pg_class WHERE relkind = 'r';
SELECT datname, age(datfrozenxid) FROM pg_database;
```

The age column measures the number of transactions from the cutoff XID to the current transaction’s XID. Immediately after a VACUUM, age(relfrozenxid) should be a little more than the vacuum_freeze_min_age setting that was used (more by the number of transactions started since the VACUUM started). If age(relfrozenxid) exceeds autovacuum_freeze_max_age, an autovacuum will soon be forced for the table.

If for some reason autovacuum fails to clear old XIDs from a table, the system will begin to emit warning messages like this when the database’s oldest XIDs reach ten million transactions from the wraparound point:
Chapter 23. Routine Database Maintenance Tasks

WARNING: database "mydb" must be vacuumed within 177009986 transactions
HINT: To avoid a database shutdown, execute a full-database VACUUM in "mydb".

If these warnings are ignored, the system will shut down and refuse to execute any new transactions once there are fewer than 1 million transactions left until wraparound:

ERROR: database is not accepting commands to avoid wraparound data loss in database "mydb"
HINT: Stop the postmaster and use a standalone backend to VACUUM in "mydb".

The 1-million-transaction safety margin exists to let the administrator recover without data loss, by manually executing the required VACUUM commands. However, since the system will not execute commands once it has gone into the safety shutdown mode, the only way to do this is to stop the server and use a single-user backend to execute VACUUM. The shutdown mode is not enforced by a single-user backend. See the postgres reference page for details about using a single-user backend.

23.1.4. The Auto-Vacuum Daemon

Beginning in PostgreSQL 8.1, there is an optional feature called autovacuum, whose purpose is to automate the execution of VACUUM and ANALYZE commands. When enabled, autovacuum checks for tables that have had a large number of inserted, updated or deleted tuples. These checks use the statistics collection facility; therefore, autovacuum cannot be used unless track_counts is set to true.

In the default configuration, autovacuuming is enabled and the related configuration parameters are appropriately set.

Beginning in PostgreSQL 8.3, autovacuum has a multiprocess architecture: There is a daemon process, called the autovacuum launcher, which is in charge of starting autovacuum worker processes for all databases. The launcher will distribute the work across time, but attempt to start one worker on each database every autovacuum_naptime seconds. One worker will be launched for each database, with a maximum of autovacuum_max_workers processes running at the same time. If there are more than autovacuum_max_workers databases to be processed, the next database will be processed as soon as the first worker finishes. The worker processes will check each table within its database and execute VACUUM and/or ANALYZE as needed.

The autovacuum_max_workers setting limits how many workers may be running at any time. If several large tables all become eligible for vacuuming in a short amount of time, all autovacuum workers may end up vacuuming those tables for a very long time. This would result in other tables and databases not being vacuumed until a worker became available. There is not a limit on how many workers might be in a single database, but workers do try to avoid repeating work that has already been done by other workers. Note that the number of running workers does not count towards the max_connections nor the superuser_reserved_connections limits.

Tables whose relfrozenxid value is more than autovacuum_freeze_max_age transactions old are always vacuumed. Otherwise, two conditions are used to determine which operation(s) to apply.

If the number of obsolete tuples since the last VACUUM exceeds the “vacuum threshold”, the table is vacuumed. The vacuum threshold is defined as:

\[
\text{vacuum threshold} = \text{vacuum base threshold} + \text{vacuum scale factor} \times \text{number of tuples}
\]

where the vacuum base threshold is autovacuum_vacuum_threshold, the vacuum scale factor is autovacuum_vacuum_scale_factor, and the number of tuples is pg_class.reltuples. The number of obsolete tuples is obtained from the statistics collector; it is a semi-accurate count updated by each UPDATE and DELETE operation. (It is only semi-accurate because some information might be lost under heavy load.) For analyze, a similar condition is used: the threshold, defined as:
analyze threshold = analyze base threshold + analyze scale factor * number of tuples

is compared to the total number of tuples inserted or updated since the last ANALYZE.

The default thresholds and scale factors are taken from postgresql.conf, but it is possible to override them on a table-by-table basis by making entries in the system catalog pg_autovacuum. If a pg_autovacuum row exists for a particular table, the settings it specifies are applied; otherwise the global settings are used. See Section 18.9 for more details on the global settings.

Besides the base threshold values and scale factors, there are five more parameters that can be set for each table in pg_autovacuum. The first, pg_autovacuum.enabled, can be set to false to instruct the autovacuum daemon to skip that particular table entirely. In this case autovacuum will only touch the table if it must do so to prevent transaction ID wraparound. The next two parameters, the vacuum cost delay (pg_autovacuum.vac_cost_delay) and the vacuum cost limit (pg_autovacuum.vac_cost_limit), are used to set table-specific values for the Cost-Based Vacuum Delay feature. The last two parameters, (pg_autovacuum.freeze_min_age) and (pg_autovacuum.freeze_max_age), are used to set table-specific values for vacuum_freeze_min_age and autovacuum_freeze_max_age respectively.

If any of the values in pg_autovacuum are set to a negative number, or if a row is not present at all in pg_autovacuum for any particular table, the corresponding values from postgresql.conf are used.

There is not currently any support for making pg_autovacuum entries, except by doing manual INSERTs into the catalog. This feature will be improved in future releases, and it is likely that the catalog definition will change.

Caution

The contents of the pg_autovacuum system catalog are currently not saved in database dumps created by the tools pg_dump and pg_dumpall. If you want to preserve them across a dump/reload cycle, make sure you dump the catalog manually.

When multiple workers are running, the cost limit is “balanced” among all the running workers, so that the total impact on the system is the same, regardless of the number of workers actually running.

23.2. Routine Reindexing

In some situations it is worthwhile to rebuild indexes periodically with the REINDEX command.

In PostgreSQL releases before 7.4, periodic reindexing was frequently necessary to avoid “index bloat”, due to lack of internal space reclamation in B-tree indexes. Any situation in which the range of index keys changed over time — for example, an index on timestamps in a table where old entries are eventually deleted — would result in bloat, because index pages for no-longer-needed portions of the key range were not reclaimed for re-use. Over time, the index size could become indefinitely much larger than the amount of useful data in it.

In PostgreSQL 7.4 and later, index pages that have become completely empty are reclaimed for re-use. There is still a possibility for inefficient use of space: if all but a few index keys on a page have been deleted, the page remains allocated. So a usage pattern in which all but a few keys in each range are eventually deleted will see poor use of space. For such usage patterns, periodic reindexing is recommended.
The potential for bloat in non-B-tree indexes has not been well characterized. It is a good idea to keep an eye on the index’s physical size when using any non-B-tree index type.

Also, for B-tree indexes a freshly-constructed index is somewhat faster to access than one that has been updated many times, because logically adjacent pages are usually also physically adjacent in a newly built index. (This consideration does not currently apply to non-B-tree indexes.) It might be worthwhile to reindex periodically just to improve access speed.

### 23.3. Log File Maintenance

It is a good idea to save the database server’s log output somewhere, rather than just routing it to /dev/null. The log output is invaluable when it comes time to diagnose problems. However, the log output tends to be voluminous (especially at higher debug levels) and you won’t want to save it indefinitely. You need to “rotate” the log files so that new log files are started and old ones removed after a reasonable period of time.

If you simply direct the stderr of postgres into a file, you will have log output, but the only way to truncate the log file is to stop and restart the server. This might be OK if you are using PostgreSQL in a development environment, but few production servers would find this behavior acceptable.

A better approach is to send the server’s stderr output to some type of log rotation program. There is a built-in log rotation program, which you can use by setting the configuration parameter `logging_collector` to `true` in `postgresql.conf`. The control parameters for this program are described in Section 18.7.1. You can also use this approach to capture the log data in machine readable CSV format.

Alternatively, you might prefer to use an external log rotation program, if you have one that you are already using with other server software. For example, the rotatelogs tool included in the Apache distribution can be used with PostgreSQL. To do this, just pipe the server’s stderr output to the desired program. If you start the server with `pg_ctl`, then stderr is already redirected to stdout, so you just need a pipe command, for example:

```
pg_ctl start | rotatelogs /var/log/pgsql_log 86400
```

Another production-grade approach to managing log output is to send it all to syslog and let syslog deal with file rotation. To do this, set the configuration parameter `log_destination` to `syslog` (to log to syslog only) in `postgresql.conf`. Then you can send a SIGHUP signal to the syslog daemon whenever you want to force it to start writing a new log file. If you want to automate log rotation, the logrotate program can be configured to work with log files from syslog.

On many systems, however, syslog is not very reliable, particularly with large log messages; it might truncate or drop messages just when you need them the most. Also, on Linux, syslog will sync each message to disk, yielding poor performance. (You can use a − at the start of the file name in the syslog configuration file to disable this behavior.)

Note that all the solutions described above take care of starting new log files at configurable intervals, but they do not handle deletion of old, no-longer-interesting log files. You will probably want to set up a batch job to periodically delete old log files. Another possibility is to configure the rotation program so that old log files are overwritten cyclically.

---

425
Chapter 24. Backup and Restore

As with everything that contains valuable data, PostgreSQL databases should be backed up regularly. While the procedure is essentially simple, it is important to have a clear understanding of the underlying techniques and assumptions.

There are three fundamentally different approaches to backing up PostgreSQL data:

- SQL dump
- File system level backup
- Continuous archiving

Each has its own strengths and weaknesses. Each is discussed in turn below.

24.1. SQL Dump

The idea behind this dump method is to generate a text file with SQL commands that, when fed back to the server, will recreate the database in the same state as it was at the time of the dump. PostgreSQL provides the utility program `pg_dump` for this purpose. The basic usage of this command is:

```
pg_dump dbname > outfile
```

As you see, `pg_dump` writes its results to the standard output. We will see below how this can be useful.

`pg_dump` is a regular PostgreSQL client application (albeit a particularly clever one). This means that you can do this backup procedure from any remote host that has access to the database. But remember that `pg_dump` does not operate with special permissions. In particular, it must have read access to all tables that you want to back up, so in practice you almost always have to run it as a database superuser.

To specify which database server `pg_dump` should contact, use the command line options `-h host` and `-p port`. The default host is the local host or whatever your `PGHOST` environment variable specifies. Similarly, the default port is indicated by the `PGPORT` environment variable or, failing that, by the compiled-in default. (Conveniently, the server will normally have the same compiled-in default.)

Like any other PostgreSQL client application, `pg_dump` will by default connect with the database user name that is equal to the current operating system user name. To override this, either specify the `-U` option or set the environment variable `PGUSER`. Remember that `pg_dump` connections are subject to the normal client authentication mechanisms (which are described in Chapter 21).

Dumps created by `pg_dump` are internally consistent, that is, the dump represents a snapshot of the database as of the time `pg_dump` begins running. `pg_dump` does not block other operations on the database while it is working. (Exceptions are those operations that need to operate with an exclusive lock, such as most forms of `ALTER TABLE`.)

**Important:** If your database schema relies on OIDs (for instance as foreign keys) you must instruct `pg_dump` to dump the OIDs as well. To do this, use the `-o` command line option.
24.1.1. Restoring the dump

The text files created by pg_dump are intended to be read in by the psql program. The general command form to restore a dump is

```plaintext
psql dbname < infile
```

where `infile` is what you used as `outfile` for the pg_dump command. The database `dbname` will not be created by this command, so you must create it yourself from `template0` before executing psql (e.g., with `createdb -T template0 dbname`). psql supports options similar to pg_dump’s for specifying the database server to connect to and the user name to use. See the psql reference page for more information.

Before restoring a SQL dump, all the users who own objects or were granted permissions on objects in the dumped database must already exist. If they do not, then the restore will fail to recreate the objects with the original ownership and/or permissions. (Sometimes this is what you want, but usually it is not.)

By default, the psql script will continue to execute after an SQL error is encountered. You might wish to use the following command at the top of the script to alter that behaviour and have psql exit with an exit status of 3 if an SQL error occurs:

```plaintext
\set ON_ERROR_STOP
```

Either way, you will have an only partially restored database. Alternatively, you can specify that the whole dump should be restored as a single transaction, so the restore is either fully completed or fully rolled back. This mode can be specified by passing the `-1` or `--single-transaction` command-line options to psql. When using this mode, be aware that even the smallest of errors can rollback a restore that has already run for many hours. However, that might still be preferable to manually cleaning up a complex database after a partially restored dump.

The ability of pg_dump and psql to write to or read from pipes makes it possible to dump a database directly from one server to another, for example:

```plaintext
pg_dump -h host1 dbname | psql -h host2 dbname
```

**Important:** The dumps produced by pg_dump are relative to `template0`. This means that any languages, procedures, etc. added via `template1` will also be dumped by pg_dump. As a result, when restoring, if you are using a customized `template1`, you must create the empty database from `template0`, as in the example above.

After restoring a backup, it is wise to run `ANALYZE` on each database so the query optimizer has useful statistics. An easy way to do this is to run `vacuumdb -a -z`; this is equivalent to running `VACUUM ANALYZE` on each database manually. For more advice on how to load large amounts of data into PostgreSQL efficiently, refer to Section 14.4.

24.1.2. Using pg_dumpall

pg_dump dumps only a single database at a time, and it does not dump information about roles or tablespaces (because those are cluster-wide rather than per-database). To support convenient dumping of the entire contents of a database cluster, the pg_dumpall program is provided. pg_dumpall backs
up each database in a given cluster, and also preserves cluster-wide data such as role and tablespace
definitions. The basic usage of this command is:

```
pg_dumpall > outfile
```

The resulting dump can be restored with psql:

```
psql -f infile postgres
```

(Actually, you can specify any existing database name to start from, but if you are reloading into an
empty cluster then `postgres` should usually be used.) It is always necessary to have database supe-
ruser access when restoring a pg_dumpall dump, as that is required to restore the role and tablespace
information. If you use tablespaces, be careful that the tablespace paths in the dump are appropriate
for the new installation.

pg_dumpall works by emitting commands to re-create roles, tablespaces, and empty databases, then
invoking pg_dump for each database. This means that while each database will be internally consist-
tent, the snapshots of different databases might not be exactly in-sync.

### 24.1.3. Handling large databases

Since PostgreSQL allows tables larger than the maximum file size on your system, it can be problem-
atric to dump such a table to a file, since the resulting file will likely be larger than the maximum size
allowed by your system. Since pg_dump can write to the standard output, you can use standard Unix
tools to work around this possible problem. There are several ways to do it:

**Use compressed dumps.** You can use your favorite compression program, for example gzip:

```
pg_dump dbname | gzip > filename.gz
```

Reload with:

```
gunzip -c filename.gz | psql dbname
```

or:

```
cat filename.gz | gunzip | psql dbname
```

**Use split.** The `split` command allows you to split the output into pieces that are acceptable in size
to the underlying file system. For example, to make chunks of 1 megabyte:

```
pg_dump dbname | split -b 1M - filename
```

Reload with:

```
cat filename* | psql dbname
```

**Use pg_dump’s custom dump format.** If PostgreSQL was built on a system with the zlib compres-
sion library installed, the custom dump format will compress data as it writes it to the output file. This
will produce dump file sizes similar to using gzip, but it has the added advantage that tables can be
restored selectively. The following command dumps a database using the custom dump format:

```
pg_dump -Fc dbname > filename
```

A custom-format dump is not a script for psql, but instead must be restored with `pg_restore`, for
example:
Chapter 24. Backup and Restore

pg_restore -d dbname filename

See the pg_dump and pg_restore reference pages for details.

For very large databases, you might need to combine split with one of the other two approaches.

24.2. File System Level Backup

An alternative backup strategy is to directly copy the files that PostgreSQL uses to store the data in the database. In Section 17.2 it is explained where these files are located, but you have probably found them already if you are interested in this method. You can use whatever method you prefer for doing usual file system backups, for example:

tar -cf backup.tar /usr/local/pgsql/data

There are two restrictions, however, which make this method impractical, or at least inferior to the pg_dump method:

1. The database server must be shut down in order to get a usable backup. Half-way measures such as disallowing all connections will not work (in part because tar and similar tools do not take an atomic snapshot of the state of the file system, but also because of internal buffering within the server). Information about stopping the server can be found in Section 17.5. Needless to say that you also need to shut down the server before restoring the data.

2. If you have dug into the details of the file system layout of the database, you might be tempted to try to back up or restore only certain individual tables or databases from their respective files or directories. This will not work because the information contained in these files contains only half the truth. The other half is in the commit log files pg_clog/*, which contain the commit status of all transactions. A table file is only usable with this information. Of course it is also impossible to restore only a table and the associated pg_clog data because that would render all other tables in the database cluster useless. So file system backups only work for complete backup and restoration of an entire database cluster.

An alternative file-system backup approach is to make a “consistent snapshot” of the data directory, if the file system supports that functionality (and you are willing to trust that it is implemented correctly). The typical procedure is to make a “frozen snapshot” of the volume containing the database, then copy the whole data directory (not just parts, see above) from the snapshot to a backup device, then release the frozen snapshot. This will work even while the database server is running. However, a backup created in this way saves the database files in a state where the database server was not properly shut down; therefore, when you start the database server on the backed-up data, it will think the previous server instance had crashed and replay the WAL log. This is not a problem, just be aware of it (and be sure to include the WAL files in your backup).

If your database is spread across multiple file systems, there might not be any way to obtain exactly-simultaneous frozen snapshots of all the volumes. For example, if your data files and WAL log are on different disks, or if tablespaces are on different file systems, it might not be possible to use snapshot backup because the snapshots must be simultaneous. Read your file system documentation very carefully before trusting to the consistent-snapshot technique in such situations. The safest approach is to shut down the database server for long enough to establish all the frozen snapshots.
Another option is to use rsync to perform a file system backup. This is done by first running rsync while the database server is running, then shutting down the database server just long enough to do a second rsync. The second rsync will be much quicker than the first, because it has relatively little data to transfer, and the end result will be consistent because the server was down. This method allows a file system backup to be performed with minimal downtime.

Note that a file system backup will not necessarily be smaller than an SQL dump. On the contrary, it will most likely be larger. (pg_dump does not need to dump the contents of indexes for example, just the commands to recreate them.) However, taking a file system backup might be faster.

### 24.3. Continuous Archiving and Point-In-Time Recovery (PITR)

At all times, PostgreSQL maintains a *write ahead log* (WAL) in the `pg_xlog/` subdirectory of the cluster’s data directory. The log describes every change made to the database’s data files. This log exists primarily for crash-safety purposes: if the system crashes, the database can be restored to consistency by “replaying” the log entries made since the last checkpoint. However, the existence of the log makes it possible to use a third strategy for backing up databases: we can combine a file-system-level backup with backup of the WAL files. If recovery is needed, we restore the backup and then replay from the backed-up WAL files to bring the backup up to current time. This approach is more complex to administer than either of the previous approaches, but it has some significant benefits:

- We do not need a perfectly consistent backup as the starting point. Any internal inconsistency in the backup will be corrected by log replay (this is not significantly different from what happens during crash recovery). So we don’t need file system snapshot capability, just tar or a similar archiving tool.

- Since we can string together an indefinitely long sequence of WAL files for replay, continuous backup can be achieved simply by continuing to archive the WAL files. This is particularly valuable for large databases, where it might not be convenient to take a full backup frequently.

- There is nothing that says we have to replay the WAL entries all the way to the end. We could stop the replay at any point and have a consistent snapshot of the database as it was at that time. Thus, this technique supports *point-in-time recovery*: it is possible to restore the database to its state at any time since your base backup was taken.

- If we continuously feed the series of WAL files to another machine that has been loaded with the same base backup file, we have a *warm standby system*: at any point we can bring up the second machine and it will have a nearly-current copy of the database.

As with the plain file-system-backup technique, this method can only support restoration of an entire database cluster, not a subset. Also, it requires a lot of archival storage: the base backup might be bulky, and a busy system will generate many megabytes of WAL traffic that have to be archived. Still, it is the preferred backup technique in many situations where high reliability is needed.

To recover successfully using continuous archiving (also called “online backup” by many database vendors), you need a continuous sequence of archived WAL files that extends back at least as far as the start time of your backup. So to get started, you should set up and test your procedure for archiving WAL files before you take your first base backup. Accordingly, we first discuss the mechanics of archiving WAL files.
Chapter 24. Backup and Restore

24.3.1. Setting up WAL archiving

In an abstract sense, a running PostgreSQL system produces an indefinitely long sequence of WAL records. The system physically divides this sequence into WAL segment files, which are normally 16MB apiece (although the segment size can be altered when building PostgreSQL). The segment files are given numeric names that reflect their position in the abstract WAL sequence. When not using WAL archiving, the system normally creates just a few segment files and then “recycles” them by renaming no-longer-needed segment files to higher segment numbers. It’s assumed that a segment file whose contents precede the checkpoint-before-last is no longer of interest and can be recycled.

When archiving WAL data, we need to capture the contents of each segment file once it is filled, and save that data somewhere before the segment file is recycled for reuse. Depending on the application and the available hardware, there could be many different ways of “saving the data somewhere”: we could copy the segment files to an NFS-mounted directory on another machine, write them onto a tape drive (ensuring that you have a way of identifying the original name of each file), or batch them together and burn them onto CDs, or something else entirely. To provide the database administrator with as much flexibility as possible, PostgreSQL tries not to make any assumptions about how the archiving will be done. Instead, PostgreSQL lets the administrator specify a shell command to be executed to copy a completed segment file to wherever it needs to go. The command could be as simple as a `cp`, or it could invoke a complex shell script — it’s all up to you.

To enable WAL archiving, set the `archive_mode` configuration parameter to `on`, and specify the shell command to use in the `archive_command` configuration parameter. In practice these settings will always be placed in the `postgresql.conf` file. In `archive_command`, any `%p` is replaced by the path name of the file to archive, while any `%f` is replaced by the file name only. (The path name is relative to the current working directory, i.e., the cluster’s data directory.) Write `%%` if you need to embed an actual `%` character in the command. The simplest useful command is something like:

```bash
archive_command = 'test ! -f /mnt/server/archivedir/%f && cp %p /mnt/server/archivedir/%f'

archive_command = 'copy "%p" "C:\server\archivedir\%f"'
```

which will copy archivable WAL segments to the directory `/mnt/server/archivedir`. (This is an example, not a recommendation, and might not work on all platforms.) After the `%p` and `%f` parameters have been replaced, the actual command executed might look like this:

```bash
test ! -f /mnt/server/archivedir/00000010000000A900000065 && cp pg_xlog/00000010000000A900000065
```

A similar command will be generated for each new file to be archived.

The archive command will be executed under the ownership of the same user that the PostgreSQL server is running as. Since the series of WAL files being archived contains effectively everything in your database, you will want to be sure that the archived data is protected from prying eyes; for example, archive into a directory that does not have group or world read access.

It is important that the archive command return zero exit status if and only if it succeeded. Upon getting a zero result, PostgreSQL will assume that the WAL segment file has been successfully archived, and will remove or recycle it. However, a nonzero status tells PostgreSQL that the file was not archived; it will try again periodically until it succeeds.

The archive command should generally be designed to refuse to overwrite any pre-existing archive file. This is an important safety feature to preserve the integrity of your archive in case of administrator error (such as sending the output of two different servers to the same archive directory).

It is advisable to test your proposed archive command to ensure that it indeed does not overwrite an existing file, and that it returns nonzero status in this case. The example command above for Unix ensures this by including a separate `test` step. On some Unix platforms, `cp` has switches such as `-i` that can be used to do the same thing less verbosely, but you should not rely on these without verifying
that the right exit status is returned. (In particular, GNU \texttt{cp} will return status zero when \texttt{-i} is used and the target file already exists, which is not the desired behavior.)

While designing your archiving setup, consider what will happen if the archive command fails repeatedly because some aspect requires operator intervention or the archive runs out of space. For example, this could occur if you write to tape without an autochanger; when the tape fills, nothing further can be archived until the tape is swapped. You should ensure that any error condition or request to a human operator is reported appropriately so that the situation can be resolved reasonably quickly. The \texttt{pg\_xlog/} directory will continue to fill with WAL segment files until the situation is resolved. (If the filesystem containing \texttt{pg\_xlog/} fills up, PostgreSQL will do a PANIC shutdown. No prior transactions will be lost, but the database will be unavailable until you free some space.)

The speed of the archiving command is not important, so long as it can keep up with the average rate at which your server generates WAL data. Normal operation continues even if the archiving process falls a little behind. If archiving falls significantly behind, this will increase the amount of data that would be lost in the event of a disaster. It will also mean that the \texttt{pg\_xlog/} directory will contain large numbers of not-yet-archived segment files, which could eventually exceed available disk space. You are advised to monitor the archiving process to ensure that it is working as you intend.

In writing your archive command, you should assume that the file names to be archived can be up to 64 characters long and can contain any combination of ASCII letters, digits, and dots. It is not necessary to remember the original relative path (\texttt{%p}) but it is necessary to remember the file name (\texttt{%f}).

Note that although WAL archiving will allow you to restore any modifications made to the data in your PostgreSQL database, it will not restore changes made to configuration files (that is, \texttt{postgresql.conf}, \texttt{pg\_hba.conf} and \texttt{pg\_ident.conf}), since those are edited manually rather than through SQL operations. You might wish to keep the configuration files in a location that will be backed up by your regular file system backup procedures. See Section 18.2 for how to relocate the configuration files.

The archive command is only invoked on completed WAL segments. Hence, if your server generates only little WAL traffic (or has slack periods where it does so), there could be a long delay between the completion of a transaction and its safe recording in archive storage. To put a limit on how old unarchived data can be, you can set \texttt{archive\_timeout} to force the server to switch to a new WAL segment file at least that often. Note that archived files that are ended early due to a forced switch are still the same length as completely full files. It is therefore unwise to set a very short \texttt{archive\_timeout} — it will bloat your archive storage. \texttt{archive\_timeout} settings of a minute or so are usually reasonable.

Also, you can force a segment switch manually with \texttt{pg\_switch\_xlog}, if you want to ensure that a just-finished transaction is archived as soon as possible. Other utility functions related to WAL management are listed in Table 9-53.

When \texttt{archive\_mode} is \texttt{off} some SQL commands are optimized to avoid WAL logging, as described in Section 14.4.7. If archiving were turned on during execution of one of these statements, WAL would not contain enough information for archive recovery. (Crash recovery is unaffected.) For this reason, \texttt{archive\_mode} can only be changed at server start. However, \texttt{archive\_command} can be changed with a configuration file reload. If you wish to temporarily stop archiving, one way to do it is to set \texttt{archive\_command} to the empty string (\texttt{""}). This will cause WAL files to accumulate in \texttt{pg\_xlog/} until a working \texttt{archive\_command} is re-established.
24.3.2. Making a Base Backup

The procedure for making a base backup is relatively simple:

1. Ensure that WAL archiving is enabled and working.

2. Connect to the database as a superuser, and issue the command:

   ```
   SELECT pg_start_backup('label');
   ```

   where `label` is any string you want to use to uniquely identify this backup operation. (One good practice is to use the full path where you intend to put the backup dump file.) `pg_start_backup` creates a backup label file, called `backup_label`, in the cluster directory with information about your backup.

   It does not matter which database within the cluster you connect to to issue this command. You can ignore the result returned by the function; but if it reports an error, deal with that before proceeding.

   `pg_start_backup` can take a long time to finish. This is because it performs a checkpoint, and the I/O required for a checkpoint will be spread out over a significant period of time, by default half your inter-checkpoint interval (see the configuration parameter `checkpoint_completion_target`). Usually this is what you want because it minimizes the impact on query processing. If you just want to start the backup as soon as possible, execute a `CHECKPOINT` command (which performs a checkpoint as quickly as possible) and then immediately execute `pg_start_backup`. Then there will be very little for `pg_start_backup`'s checkpoint to do, and it won’t take long.

3. Perform the backup, using any convenient file-system-backup tool such as tar or cpio. It is neither necessary nor desirable to stop normal operation of the database while you do this.

4. Again connect to the database as a superuser, and issue the command:

   ```
   SELECT pg_stop_backup();
   ```

   This terminates the backup mode and performs an automatic switch to the next WAL segment. The reason for the switch is to arrange that the last WAL segment file written during the backup interval is immediately ready to archive.

5. Once the WAL segment files used during the backup are archived, you are done. The file identified by `pg_stop_backup`'s result is the last segment that needs to be archived to complete the backup. Archival of these files will happen automatically, since you have already configured `archive_command`. In many cases, this happens fairly quickly, but you are advised to monitor your archival system to ensure this has taken place so that you can be certain you have a complete backup.

Some backup tools that you might wish to use emit warnings or errors if the files they are trying to copy change while the copy proceeds. This situation is normal, and not an error, when taking a base backup of an active database; so you need to ensure that you can distinguish complaints of this sort from real errors. For example, some versions of rsync return a separate exit code for “vanished source files”, and you can write a driver script to accept this exit code as a non-error case. Also, some versions of GNU tar return an error code indistinguishable from a fatal error if a file was truncated while tar was copying it. Fortunately, GNU tar versions 1.16 and later exit with 1 if a file was changed during the backup, and 2 for other errors.

It is not necessary to be very concerned about the amount of time elapsed between `pg_start_backup` and the start of the actual backup, nor between the end of the backup and `pg_stop_backup`; a few minutes’ delay won’t hurt anything. (However, if you normally run the
server with `full_page_writes` disabled, you might notice a drop in performance between `pg_start_backup` and `pg_stop_backup`, since `full_page_writes` is effectively forced on during backup mode.) You must ensure that these steps are carried out in sequence without any possible overlap, or you will invalidate the backup.

Be certain that your backup dump includes all of the files underneath the database cluster directory (e.g., `/usr/local/pgsql/data`). If you are using tablespaces that do not reside underneath this directory, be careful to include them as well (and be sure that your backup dump archives symbolic links as links, otherwise the restore will mess up your tablespaces).

You can, however, omit from the backup dump the files within the `pg_xlog/` subdirectory of the cluster directory. This slight complication is worthwhile because it reduces the risk of mistakes when restoring. This is easy to arrange if `pg_xlog/` is a symbolic link pointing to someplace outside the cluster directory, which is a common setup anyway for performance reasons.

To make use of the backup, you will need to keep around all the WAL segment files generated during and after the file system backup. To aid you in doing this, the `pg_stop_backup` function creates a backup history file that is immediately stored into the WAL archive area. This file is named after the first WAL segment file that you need to have to make use of the backup. For example, if the starting WAL file is `000000100001234000055CD` the backup history file will be named something like `000000100001234000055CD.007C9330.backup`. (The second part of the file name stands for an exact position within the WAL file, and can ordinarily be ignored.) Once you have safely archived the file system backup and the WAL segment files used during the backup (as specified in the backup history file), all archived WAL segments with names numerically less are no longer needed to recover the file system backup and can be deleted. However, you should consider keeping several backup sets to be absolutely certain that you can recover your data.

The backup history file is just a small text file. It contains the label string you gave to `pg_start_backup`, as well as the starting and ending times and WAL segments of the backup. If you used the label to identify where the associated dump file is kept, then the archived history file is enough to tell you which dump file to restore, should you need to do so.

Since you have to keep around all the archived WAL files back to your last base backup, the interval between base backups should usually be chosen based on how much storage you want to expend on archived WAL files. You should also consider how long you are prepared to spend recovering, if recovery should be necessary — the system will have to replay all those WAL segments, and that could take awhile if it has been a long time since the last base backup.

It’s also worth noting that the `pg_start_backup` function makes a file named `backup_label` in the database cluster directory, which is then removed again by `pg_stop_backup`. This file will of course be archived as a part of your backup dump file. The backup label file includes the label string you gave to `pg_start_backup`, as well as the time at which `pg_start_backup` was run, and the name of the starting WAL file. In case of confusion it will therefore be possible to look inside a backup dump file and determine exactly which backup session the dump file came from.

It is also possible to make a backup dump while the server is stopped. In this case, you obviously cannot use `pg_start_backup` or `pg_stop_backup`, and you will therefore be left to your own devices to keep track of which backup dump is which and how far back the associated WAL files go. It is generally better to follow the continuous archiving procedure above.
24.3.3. Recovering using a Continuous Archive Backup

Okay, the worst has happened and you need to recover from your backup. Here is the procedure:

1. Stop the server, if it’s running.

2. If you have the space to do so, copy the whole cluster data directory and any tablespaces to a temporary location in case you need them later. Note that this precaution will require that you have enough free space on your system to hold two copies of your existing database. If you do not have enough space, you need at least to copy the contents of the pg_xlog subdirectory of the cluster data directory, as it might contain logs which were not archived before the system went down.

3. Clean out all existing files and subdirectories under the cluster data directory and under the root directories of any tablespaces you are using.

4. Restore the database files from your backup dump. Be careful that they are restored with the right ownership (the database system user, not root!) and with the right permissions. If you are using tablespaces, you should verify that the symbolic links in pg_tblspc/ were correctly restored.

5. Remove any files present in pg_xlog/; these came from the backup dump and are therefore probably obsolete rather than current. If you didn’t archive pg_xlog/ at all, then recreate it, being careful to ensure that you re-establish it as a symbolic link if you had it set up that way before. Be sure to recreate the subdirectory pg_xlog/archive_status/ as well.

6. If you had unarchived WAL segment files that you saved in step 2, copy them into pg_xlog/.
   (It is best to copy them, not move them, so that you still have the unmodified files if a problem occurs and you have to start over.)

7. Create a recovery command file recovery.conf in the cluster data directory (see Recovery Settings). You might also want to temporarily modify pg_hba.conf to prevent ordinary users from connecting until you are sure the recovery has worked.

8. Start the server. The server will go into recovery mode and proceed to read through the archived WAL files it needs. Should the recovery be terminated because of an external error, the server can simply be restarted and it will continue recovery. Upon completion of the recovery process, the server will rename recovery.conf to recovery.done (to prevent accidentally re-entering recovery mode in case of a crash later) and then commence normal database operations.

9. Inspect the contents of the database to ensure you have recovered to where you want to be. If not, return to step 1. If all is well, let in your users by restoring pg_hba.conf to normal.

The key part of all this is to set up a recovery command file that describes how you want to recover and how far the recovery should run. You can use recovery.conf.sample (normally installed in the installation share/ directory) as a prototype. The one thing that you absolutely must specify in recovery.conf is the restore_command, which tells PostgreSQL how to get back archived WAL file segments. Like the archive_command, this is a shell command string. It can contain %f, which is replaced by the name of the desired log file, and %p, which is replaced by the path name to copy the log file to. (The path name is relative to the current working directory, i.e., the cluster’s data directory.) Write % if you need to embed an actual % character in the command. The simplest useful command is something like:

```bash
restore_command = 'cp /mnt/server/archivedir/%f %p'
```

which will copy previously archived WAL segments from the directory /mnt/server/archivedir. You could of course use something much more complicated, perhaps even a shell script that requests
Chapter 24. Backup and Restore

the operator to mount an appropriate tape.

It is important that the command return nonzero exit status on failure. The command will be asked for log files that are not present in the archive; it must return nonzero when so asked. This is not an error condition. Be aware also that the base name of the %p path will be different from %f; do not expect them to be interchangeable.

WAL segments that cannot be found in the archive will be sought in pg_xlog/; this allows use of recent un-archived segments. However segments that are available from the archive will be used in preference to files in pg_xlog/. The system will not overwrite the existing contents of pg_xlog/ when retrieving archived files.

Normally, recovery will proceed through all available WAL segments, thereby restoring the database to the current point in time (or as close as we can get given the available WAL segments). So a normal recovery will end with a “file not found” message, the exact text of the error message depending upon your choice of restore_command. You may also see an error message at the start of recovery for a file named something like 00000001.history. This is also normal and does not indicate a problem in simple recovery situations. See Section 24.3.4 for discussion.

If you want to recover to some previous point in time (say, right before the junior DBA dropped your main transaction table), just specify the required stopping point in recovery.conf. You can specify the stop point, known as the “recovery target”, either by date/time or by completion of a specific transaction ID. As of this writing only the date/time option is very usable, since there are no tools to help you identify with any accuracy which transaction ID to use.

Note: The stop point must be after the ending time of the base backup, i.e., the time of pg_stop_backup. You cannot use a base backup to recover to a time when that backup was still going on. (To recover to such a time, you must go back to your previous base backup and roll forward from there.)

If recovery finds a corruption in the WAL data then recovery will complete at that point and the server will not start. In such a case the recovery process could be re-run from the beginning, specifying a “recovery target” before the point of corruption so that recovery can complete normally. If recovery fails for an external reason, such as a system crash or if the WAL archive has become inaccessible, then the recovery can simply be restarted and it will restart almost from where it failed. Recovery restart works much like checkpointing in normal operation: the server periodically forces all its state to disk, and then updates the pg_control file to indicate that the already-processed WAL data need not be scanned again.

24.3.3.1. Recovery Settings

These settings can only be made in the recovery.conf file, and apply only for the duration of the recovery. They must be reset for any subsequent recovery you wish to perform. They cannot be changed once recovery has begun.

restore_command(string)

The shell command to execute to retrieve an archived segment of the WAL file series. This parameter is required. Any %f in the string is replaced by the name of the file to retrieve from the archive, and any %p is replaced by the path name to copy it to on the server. (The path name is relative to the current working directory, i.e., the cluster’s data directory.) Any %r is replaced by the name of the file containing the last valid restart point. That is the earliest file that must be kept to allow a restore to be restartable, so this information can be used to truncate the archive to just the minimum required to support restart of the current restore. %r would only be used in
Chapter 24. Backup and Restore

a warm-standby configuration (see Section 24.4). Write `%` to embed an actual `%` character in the command.

It is important for the command to return a zero exit status if and only if it succeeds. The command will be asked for file names that are not present in the archive; it must return nonzero when so asked. Examples:

```bash
restore_command = 'cp /mnt/server/archivedir/%f "%p"
restore_command = 'copy "C:\server\archivedir\%f" "%p"' # Windows
```

`recovery_target_time` (timestamp)

This parameter specifies the time stamp up to which recovery will proceed. At most one of `recovery_target_time` and `recovery_target_xid` can be specified. The default is to recover to the end of the WAL log. The precise stopping point is also influenced by `recovery_target_inclusive`.

`recovery_target_xid` (string)

This parameter specifies the transaction ID up to which recovery will proceed. Keep in mind that while transaction IDs are assigned sequentially at transaction start, transactions can complete in a different numeric order. The transactions that will be recovered are those that committed before (and optionally including) the specified one. At most one of `recovery_target_xid` and `recovery_target_time` can be specified. The default is to recover to the end of the WAL log. The precise stopping point is also influenced by `recovery_target_inclusive`.

`recovery_target_inclusive` (boolean)

Specifies whether we stop just after the specified recovery target (true), or just before the recovery target (false). Applies to both `recovery_target_time` and `recovery_target_xid`, whichever one is specified for this recovery. This indicates whether transactions having exactly the target commit time or ID, respectively, will be included in the recovery. Default is true.

`recovery_target_timeline` (string)

Specifies recovering into a particular timeline. The default is to recover along the same timeline that was current when the base backup was taken. You would only need to set this parameter in complex re-recovery situations, where you need to return to a state that itself was reached after a point-in-time recovery. See Section 24.3.4 for discussion.

`log_restartpoints` (boolean)

Specifies whether to log each restart point as it occurs. This can be helpful to track the progress of a long recovery. Default is false.

24.3.4. Timelines

The ability to restore the database to a previous point in time creates some complexities that are akin to science-fiction stories about time travel and parallel universes. In the original history of the database, perhaps you dropped a critical table at 5:15PM on Tuesday evening, but didn’t realize your mistake until Wednesday noon. Unfazed, you get out your backup, restore to the point-in-time 5:14PM Tuesday evening, and are up and running. In this history of the database universe, you never dropped the table at all. But suppose you later realize this wasn’t such a great idea after all, and would like to return to sometime Wednesday morning in the original history. You won’t be able to if, while your database was up-and-running, it overwrote some of the sequence of WAL segment files that led up to the time you now wish you could get back to. So you really want to distinguish the series of WAL
records generated after you’ve done a point-in-time recovery from those that were generated in the original database history.

To deal with these problems, PostgreSQL has a notion of timelines. Whenever an archive recovery is completed, a new timeline is created to identify the series of WAL records generated after that recovery. The timeline ID number is part of WAL segment file names, and so a new timeline does not overwrite the WAL data generated by previous timelines. It is in fact possible to archive many different timelines. While that might seem like a useless feature, it’s often a lifesaver. Consider the situation where you aren’t quite sure what point-in-time to recover to, and so have to do several point-in-time recoveries by trial and error until you find the best place to branch off from the old history. Without timelines this process would soon generate an unmanageable mess. With timelines, you can recover to any prior state, including states in timeline branches that you later abandoned.

Each time a new timeline is created, PostgreSQL creates a “timeline history” file that shows which timeline it branched off from and when. These history files are necessary to allow the system to pick the right WAL segment files when recovering from an archive that contains multiple timelines. Therefore, they are archived into the WAL archive area just like WAL segment files. The history files are just small text files, so it’s cheap and appropriate to keep them around indefinitely (unlike the segment files which are large). You can, if you like, add comments to a history file to make your own notes about how and why this particular timeline came to be. Such comments will be especially valuable when you have a thicket of different timelines as a result of experimentation.

The default behavior of recovery is to recover along the same timeline that was current when the base backup was taken. If you want to recover into some child timeline (that is, you want to return to some state that was itself generated after a recovery attempt), you need to specify the target timeline ID in recovery.conf. You cannot recover into timelines that branched off earlier than the base backup.

### 24.3.5. Tips and Examples

Some tips for configuring continuous archiving are given here.

#### 24.3.5.1. Standalone hot backups

It is possible to use PostgreSQL’s backup facilities to produce standalone hot backups. These are backups that cannot be used for point-in-time recovery, yet are typically much faster to backup and restore than pg_dump dumps. (They are also much larger than pg_dump dumps, so in some cases the speed advantage could be negated.)

To prepare for standalone hot backups, set `archive_mode` to on, and set up an `archive_command` that performs archiving only when a “switch file” exists. For example:

```
archive_command = 'test ! -f /var/lib/pgsql/backup_in_progress || (test ! -f /var/lib/pgsql/archive/%f && cp %p /var/lib/pgsql/archive/%f)
```

This command will perform archiving when `/var/lib/pgsql/backup_in_progress` exists, and otherwise silently return zero exit status (allowing PostgreSQL to recycle the unwanted WAL file).

With this preparation, a backup can be taken using a script like the following:

```
touch /var/lib/pgsql/backup_in_progress
psql -c "select pg_start_backup('hot_backup');"
tar -cf /var/lib/pgsql/backup.tar /var/lib/pgsql/data/
psql -c "select pg_stop_backup();"
sleep 20
rm /var/lib/pgsql/backup_in_progress
```

```
tar -rf /var/lib/pgsql/backup.tar /var/lib/pgsql/archive/
```
Chapter 24. Backup and Restore

The switch file /var/lib/pgsql/backup_in_progress is created first, enabling archiving of completed WAL files to occur. After the backup the switch file is removed. Archived WAL files are then added to the backup so that both base backup and all required WAL files are part of the same tar file.

24.3.5.2. archive_command scripts

Many people choose to use scripts to define their archive_command, so that their postgresql.conf entry looks very simple:

```
archive_command = 'local_backup_script.sh "%p" "%f"
```

Using a separate script file is advisable any time you want to use more than a single command in the archiving process. This allows all complexity to be managed within the script, which can be written in a popular scripting language such as bash or perl.

Examples of requirements that might be solved within a script include:

- Copying data to secure off-site data storage
- Batching WAL files so that they are transferred every three hours, rather than one at a time
- Interfacing with other backup and recovery software
- Interfacing with monitoring software to report errors

**Tip:** When using an archive_command script, it’s desirable to enable logging_collector. Any messages written to stderr from the script will then appear in the database server log, allowing complex configurations to be diagnosed easily if they fail.

24.3.6. Caveats

At this writing, there are several limitations of the continuous archiving technique. These will probably be fixed in future releases:

- Operations on hash indexes are not presently WAL-logged, so replay will not update these indexes. The recommended workaround is to manually `REINDEX` each such index after completing a recovery operation.
- If a `CREATE DATABASE` command is executed while a base backup is being taken, and then the template database that the `CREATE DATABASE` copied is modified while the base backup is still in progress, it is possible that recovery will cause those modifications to be propagated into the created database as well. This is of course undesirable. To avoid this risk, it is best not to modify any template databases while taking a base backup.
- `CREATE TABLESPACE` commands are WAL-logged with the literal absolute path, and will therefore be replayed as tablespace creations with the same absolute path. This might be undesirable if the log is being replayed on a different machine. It can be dangerous even if the log is being replayed on the same machine, but into a new data directory: the replay will still overwrite the
Chapter 24. Backup and Restore

contents of the original tablespace. To avoid potential gotchas of this sort, the best practice is to take a new base backup after creating or dropping tablespaces.

It should also be noted that the default WAL format is fairly bulky since it includes many disk page snapshots. These page snapshots are designed to support crash recovery, since we might need to fix partially-written disk pages. Depending on your system hardware and software, the risk of partial writes might be small enough to ignore, in which case you can significantly reduce the total volume of archived logs by turning off page snapshots using the full_page_writes parameter. (Read the notes and warnings in Chapter 28 before you do so.) Turning off page snapshots does not prevent use of the logs for PITR operations. An area for future development is to compress archived WAL data by removing unnecessary page copies even when full_page_writes is on. In the meantime, administrators might wish to reduce the number of page snapshots included in WAL by increasing the checkpoint interval parameters as much as feasible.

24.4. Warm Standby Servers for High Availability

Continuous archiving can be used to create a high availability (HA) cluster configuration with one or more standby servers ready to take over operations if the primary server fails. This capability is widely referred to as warm standby or log shipping.

The primary and standby server work together to provide this capability, though the servers are only loosely coupled. The primary server operates in continuous archiving mode, while each standby server operates in continuous recovery mode, reading the WAL files from the primary. No changes to the database tables are required to enable this capability, so it offers low administration overhead in comparison with some other replication approaches. This configuration also has relatively low performance impact on the primary server.

Directly moving WAL records from one database server to another is typically described as log shipping. PostgreSQL implements file-based log shipping, which means that WAL records are transferred one file (WAL segment) at a time. WAL files (16MB) can be shipped easily and cheaply over any distance, whether it be to an adjacent system, another system on the same site or another system on the far side of the globe. The bandwidth required for this technique varies according to the transaction rate of the primary server. Record-based log shipping is also possible with custom-developed procedures, as discussed in Section 24.4.4.

It should be noted that the log shipping is asynchronous, i.e. the WAL records are shipped after transaction commit. As a result there is a window for data loss should the primary server suffer a catastrophic failure: transactions not yet shipped will be lost. The length of the window of data loss can be limited by use of the archive_timeout parameter, which can be set as low as a few seconds if required. However such low settings will substantially increase the bandwidth requirements for file shipping. If you need a window of less than a minute or so, it’s probably better to look into record-based log shipping.

The standby server is not available for access, since it is continually performing recovery processing. Recovery performance is sufficiently good that the standby will typically be only moments away from full availability once it has been activated. As a result, we refer to this capability as a warm standby configuration that offers high availability. Restoring a server from an archived base backup and rollforward will take considerably longer, so that technique only offers a solution for disaster recovery, not high availability.
24.4.1. Planning

It is usually wise to create the primary and standby servers so that they are as similar as possible, at least from the perspective of the database server. In particular, the path names associated with tablespaces will be passed across as-is, so both primary and standby servers must have the same mount paths for tablespaces if that feature is used. Keep in mind that if `CREATE TABLESPACE` is executed on the primary, any new mount point needed for it must be created on both the primary and all standby servers before the command is executed. Hardware need not be exactly the same, but experience shows that maintaining two identical systems is easier than maintaining two dissimilar ones over the lifetime of the application and system. In any case the hardware architecture must be the same — shipping from, say, a 32-bit to a 64-bit system will not work.

In general, log shipping between servers running different major PostgreSQL release levels will not be possible. It is the policy of the PostgreSQL Global Development Group not to make changes to disk formats during minor release upgrades, so it is likely that running different minor release levels on primary and standby servers will work successfully. However, no formal support for that is offered and you are advised to keep primary and standby servers at the same release level as much as possible. When updating to a new minor release, the safest policy is to update the standby servers first — a new minor release is more likely to be able to read WAL files from a previous minor release than vice versa.

There is no special mode required to enable a standby server. The operations that occur on both primary and standby servers are entirely normal continuous archiving and recovery tasks. The only point of contact between the two database servers is the archive of WAL files that both share: primary writing to the archive, standby reading from the archive. Care must be taken to ensure that WAL archives for separate primary servers do not become mixed together or confused. The archive need not be large, if it is only required for the standby operation.

The magic that makes the two loosely coupled servers work together is simply a `restore_command` used on the standby that waits for the next WAL file to become available from the primary. The `restore_command` is specified in the `recovery.conf` file on the standby server. Normal recovery processing would request a file from the WAL archive, reporting failure if the file was unavailable. For standby processing it is normal for the next file to be unavailable, so we must be patient and wait for it to appear. A waiting `restore_command` can be written as a custom script that loops after polling for the existence of the next WAL file. There must also be some way to trigger failover, which should interrupt the `restore_command`, break the loop and return a file-not-found error to the standby server. This ends recovery and the standby will then come up as a normal server.

Pseudocode for a suitable `restore_command` is:

```c
triggered = false;
while (!NextWALFileReady() && !triggered)
{
    sleep(100000L); // wait for ~0.1 sec */
    if (CheckForExternalTrigger())
        triggered = true;
}
if (!triggered)
    CopyWALFileForRecovery();
```

A working example of a waiting `restore_command` is provided as a `contrib` module named `pg_standby`. This example can be extended as needed to support specific configurations or environments.
Chapter 24. Backup and Restore

PostgreSQL does not provide the system software required to identify a failure on the primary and notify the standby system and then the standby database server. Many such tools exist and are well integrated with other aspects required for successful failover, such as IP address migration.

The means for triggering failover is an important part of planning and design. The `restore_command` is executed in full once for each WAL file. The process running the `restore_command` is therefore created and dies for each file, so there is no daemon or server process and so we cannot use signals and a signal handler. A more permanent notification is required to trigger the failover. It is possible to use a simple timeout facility, especially if used in conjunction with a known `archive_timeout` setting on the primary. This is somewhat error prone since a network problem or busy primary server might be sufficient to initiate failover. A notification mechanism such as the explicit creation of a trigger file is less error prone, if this can be arranged.

The size of the WAL archive can be minimized by using the `%r` option of the `restore_command`. This option specifies the last archive file name that needs to be kept to allow the recovery to restart correctly. This can be used to truncate the archive once files are no longer required, if the archive is writable from the standby server.

### 24.4.2. Implementation

The short procedure for configuring a standby server is as follows. For full details of each step, refer to previous sections as noted.

1. Set up primary and standby systems as near identically as possible, including two identical copies of PostgreSQL at the same release level.

2. Set up continuous archiving from the primary to a WAL archive located in a directory on the standby server. Ensure that `archive_mode`, `archive_command` and `archive_timeout` are set appropriately on the primary (see Section 24.3.1).

3. Make a base backup of the primary server (see Section 24.3.2), and load this data onto the standby.

4. Begin recovery on the standby server from the local WAL archive, using a `recovery.conf` that specifies a `restore_command` that waits as described previously (see Section 24.3.3).

Recovery treats the WAL archive as read-only, so once a WAL file has been copied to the standby system it can be copied to tape at the same time as it is being read by the standby database server. Thus, running a standby server for high availability can be performed at the same time as files are stored for longer term disaster recovery purposes.

For testing purposes, it is possible to run both primary and standby servers on the same system. This does not provide any worthwhile improvement in server robustness, nor would it be described as HA.

### 24.4.3. Failover

If the primary server fails then the standby server should begin failover procedures.

If the standby server fails then no failover need take place. If the standby server can be restarted, even some time later, then the recovery process can also be immediately restarted, taking advantage of restartable recovery. If the standby server cannot be restarted, then a full new standby server instance should be created.
If the primary server fails and then immediately restarts, you must have a mechanism for informing it that it is no longer the primary. This is sometimes known as STONITH (Shoot the Other Node In The Head), which is necessary to avoid situations where both systems think they are the primary, which will lead to confusion and ultimately data loss.

Many failover systems use just two systems, the primary and the standby, connected by some kind of heartbeat mechanism to continually verify the connectivity between the two and the viability of the primary. It is also possible to use a third system (called a witness server) to prevent some cases of inappropriate failover, but the additional complexity might not be worthwhile unless it is set up with sufficient care and rigorous testing.

Once failover to the standby occurs, we have only a single server in operation. This is known as a degenerate state. The former standby is now the primary, but the former primary is down and might stay down. To return to normal operation we must fully recreate a standby server, either on the former primary system when it comes up, or on a third, possibly new, system. Once complete the primary and standby can be considered to have switched roles. Some people choose to use a third server to provide backup to the new primary until the new standby server is recreated, though clearly this complicates the system configuration and operational processes.

So, switching from primary to standby server can be fast but requires some time to re-prepare the failover cluster. Regular switching from primary to standby is useful, since it allows regular downtime on each system for maintenance. This also serves as a test of the failover mechanism to ensure that it will really work when you need it. Written administration procedures are advised.

### 24.4.4. Record-based Log Shipping

PostgreSQL directly supports file-based log shipping as described above. It is also possible to implement record-based log shipping, though this requires custom development.

An external program can call the `pg_xlogfile_name_offset()` function (see Section 9.23) to find out the file name and the exact byte offset within it of the current end of WAL. It can then access the WAL file directly and copy the data from the last known end of WAL through the current end over to the standby server(s). With this approach, the window for data loss is the polling cycle time of the copying program, which can be very small, but there is no wasted bandwidth from forcing partially-used segment files to be archived. Note that the standby servers’ `restore_command` scripts still deal in whole WAL files, so the incrementally copied data is not ordinarily made available to the standby servers. It is of use only when the primary dies — then the last partial WAL file is fed to the standby before allowing it to come up. So correct implementation of this process requires cooperation of the `restore_command` script with the data copying program.

### 24.5. Migration Between Releases

This section discusses how to migrate your database data from one PostgreSQL release to a newer one. The software installation procedure *per se* is not the subject of this section; those details are in Chapter 15.

As a general rule, the internal data storage format is subject to change between major releases of PostgreSQL (where the number after the first dot changes). This does not apply to different minor releases under the same major release (where the number after the second dot changes); these always have compatible storage formats. For example, releases 8.1.1, 8.2.3, and 8.3 are not compatible, whereas 8.2.3 and 8.2.4 are. When you update between compatible versions, you can simply replace
Chapter 24. Backup and Restore

the executables and reuse the data directory on disk. Otherwise you need to back up your data and restore it on the new server. This has to be done using pg_dump; file system level backup methods obviously won’t work. There are checks in place that prevent you from using a data directory with an incompatible version of PostgreSQL, so no great harm can be done by trying to start the wrong server version on a data directory.

It is recommended that you use the pg_dump and pg_dumpall programs from the newer version of PostgreSQL, to take advantage of any enhancements that might have been made in these programs. Current releases of the dump programs can read data from any server version back to 7.0.

The least downtime can be achieved by installing the new server in a different directory and running both the old and the new servers in parallel, on different ports. Then you can use something like:

```bash
pg_dumpall -p 5432 | psql -d postgres -p 6543
```

to transfer your data. Or use an intermediate file if you want. Then you can shut down the old server and start the new server at the port the old one was running at. You should make sure that the old database is not updated after you begin to run pg_dumpall, otherwise you will lose that data. See Chapter 21 for information on how to prohibit access.

It is also possible to use replication methods, such as Slony, to create a slave server with the updated version of PostgreSQL. The slave can be on the same computer or a different computer. Once it has synced up with the master server (running the older version of PostgreSQL), you can switch masters and make the slave the master and shut down the older database instance. Such a switch-over results in only several seconds of downtime for an upgrade.

In practice you probably want to test your client applications on the new setup before switching over completely. This is another reason for setting up concurrent installations of old and new versions.

If you cannot or do not want to run two servers in parallel, you can do the backup step before installing the new version, bring down the server, move the old version out of the way, install the new version, start the new server, and restore the data. For example:

```bash
pg_dumpall > backup
pg_ctl stop
mv /usr/local/pgsql /usr/local/pgsql.old
cd ~/postgresql-8.3.23
gmake install
initdb -D /usr/local/pgsql/data
postgres -D /usr/local/pgsql/data
psql -f backup postgres
```

See Chapter 17 about ways to start and stop the server and other details. The installation instructions will advise you of strategic places to perform these steps.

**Note:** When you “move the old installation out of the way” it might no longer be perfectly usable. Some of the executable programs contain absolute paths to various installed programs and data files. This is usually not a big problem, but if you plan on using two installations in parallel for a while you should assign them different installation directories at build time. (This problem is rectified in PostgreSQL 8.0 and later, so long as you move all subdirectories containing installed files together; for example if `/usr/local/postgres/bin/` goes to `/usr/local/postgres.old/bin/`, then `/usr/local/postgres/share/` must go to `/usr/local/postgres.old/share/`. In pre-8.0 releases moving an installation like this will not work.)
Chapter 25. High Availability, Load Balancing, and Replication

Database servers can work together to allow a second server to take over quickly if the primary server fails (high availability), or to allow several computers to serve the same data (load balancing). Ideally, database servers could work together seamlessly. Web servers serving static web pages can be combined quite easily by merely load-balancing web requests to multiple machines. In fact, read-only database servers can be combined relatively easily too. Unfortunately, most database servers have a read/write mix of requests, and read/write servers are much harder to combine. This is because though read-only data needs to be placed on each server only once, a write to any server has to be propagated to all servers so that future read requests to those servers return consistent results.

This synchronization problem is the fundamental difficulty for servers working together. Because there is no single solution that eliminates the impact of the sync problem for all use cases, there are multiple solutions. Each solution addresses this problem in a different way, and minimizes its impact for a specific workload.

Some solutions deal with synchronization by allowing only one server to modify the data. Servers that can modify data are called read/write or "master" servers. Servers that can reply to read-only queries are called "slave" servers. Servers that cannot be accessed until they are changed to master servers are called "standby" servers.

Some solutions are synchronous, meaning that a data-modifying transaction is not considered committed until all servers have committed the transaction. This guarantees that a failover will not lose any data and that all load-balanced servers will return consistent results no matter which server is queried. In contrast, asynchronous solutions allow some delay between the time of a commit and its propagation to the other servers, opening the possibility that some transactions might be lost in the switch to a backup server, and that load balanced servers might return slightly stale results. Asynchronous communication is used when synchronous would be too slow.

Solutions can also be categorized by their granularity. Some solutions can deal only with an entire database server, while others allow control at the per-table or per-database level.

Performance must be considered in any choice. There is usually a trade-off between functionality and performance. For example, a full synchronous solution over a slow network might cut performance by more than half, while an asynchronous one might have a minimal performance impact.

The remainder of this section outlines various failover, replication, and load balancing solutions. A glossary¹ is also available.

Shared Disk Failover

Shared disk failover avoids synchronization overhead by having only one copy of the database. It uses a single disk array that is shared by multiple servers. If the main database server fails, the standby server is able to mount and start the database as though it was recovering from a database crash. This allows rapid failover with no data loss.

Shared hardware functionality is common in network storage devices. Using a network file system is also possible, though care must be taken that the file system has full POSIX behavior (see Section 17.2.1). One significant limitation of this method is that if the shared disk array fails or becomes corrupt, the primary and standby servers are both nonfunctional. Another issue is that the standby server should never access the shared storage while the primary server is running.

¹. http://www.postgres-r.org/documentation/terms
Chapter 25. High Availability, Load Balancing, and Replication

File System (Block-Device) Replication

A modified version of shared hardware functionality is file system replication, where all changes to a file system are mirrored to a file system residing on another computer. The only restriction is that the mirroring must be done in a way that ensures the standby server has a consistent copy of the file system — specifically, writes to the standby must be done in the same order as those on the master. DRBD is a popular file system replication solution for Linux.

Warm Standby Using Point-In-Time Recovery (PITR)

A warm standby server (see Section 24.4) can be kept current by reading a stream of write-ahead log (WAL) records. If the main server fails, the warm standby contains almost all of the data of the main server, and can be quickly made the new master database server. This is asynchronous and can only be done for the entire database server.

Master-Slave Replication

A master-slave replication setup sends all data modification queries to the master server. The master server asynchronously sends data changes to the slave server. The slave can answer read-only queries while the master server is running. The slave server is ideal for data warehouse queries.

Slony-I is an example of this type of replication, with per-table granularity, and support for multiple slaves. Because it updates the slave server asynchronously (in batches), there is possible data loss during fail over.

Statement-Based Replication Middleware

With statement-based replication middleware, a program intercepts every SQL query and sends it to one or all servers. Each server operates independently. Read-write queries are sent to all servers, while read-only queries can be sent to just one server, allowing the read workload to be distributed.

If queries are simply broadcast unmodified, functions like `random()`, `CURRENT_TIMESTAMP`, and sequences would have different values on different servers. This is because each server operates independently, and because SQL queries are broadcast (and not actual modified rows). If this is unacceptable, either the middleware or the application must query such values from a single server and then use those values in write queries. Also, care must be taken that all transactions either commit or abort on all servers, perhaps using two-phase commit (`PREPARE TRANSACTION` and `COMMIT PREPARED`). Pgpool-II and Sequoia are examples of this type of replication.

Asynchronous Multimaster Replication

For servers that are not regularly connected, like laptops or remote servers, keeping data consistent among servers is a challenge. Using asynchronous multimaster replication, each server works independently, and periodically communicates with the other servers to identify conflicting transactions. The conflicts can be resolved by users or conflict resolution rules.

Synchronous Multimaster Replication

In synchronous multimaster replication, each server can accept write requests, and modified data is transmitted from the original server to every other server before each transaction commits. Heavy write activity can cause excessive locking, leading to poor performance. In fact, write performance is often worse than that of a single server. Read requests can be sent to any server. Some implementations use shared disk to reduce the communication overhead. Synchronous multimaster replication is best for mostly read workloads, though its big advantage is that any server can accept write requests — there is no need to partition workloads between master and slave servers, and because the data changes are sent from one server to another, there is no problem with non-deterministic functions like `random()`.
Chapter 25. High Availability, Load Balancing, and Replication

PostgreSQL does not offer this type of replication, though PostgreSQL two-phase commit (*PREPARE TRANSACTION* and *COMMIT PREPARED*) can be used to implement this in application code or middleware.

**Commercial Solutions**

Because PostgreSQL is open source and easily extended, a number of companies have taken PostgreSQL and created commercial closed-source solutions with unique failover, replication, and load balancing capabilities.

Table 25-1 summarizes the capabilities of the various solutions listed above.

There are a few solutions that do not fit into the above categories:

Data Partitioning

Data partitioning splits tables into data sets. Each set can be modified by only one server. For example, data can be partitioned by offices, e.g. London and Paris, with a server in each office. If queries combining London and Paris data are necessary, an application can query both servers, or master/slave replication can be used to keep a read-only copy of the other office’s data on each server.

Multiple-Server Parallel Query Execution

Many of the above solutions allow multiple servers to handle multiple queries, but none allow a single query to use multiple servers to complete faster. This solution allows multiple servers to work concurrently on a single query. It is usually accomplished by splitting the data among servers and having each server execute its part of the query and return results to a central server where they are combined and returned to the user. Pgpool-II has this capability. Also, this can be implemented using the PL/Proxy toolset.
Chapter 26. Monitoring Database Activity

A database administrator frequently wonders, “What is the system doing right now?” This chapter discusses how to find that out.

Several tools are available for monitoring database activity and analyzing performance. Most of this chapter is devoted to describing PostgreSQL’s statistics collector, but one should not neglect regular Unix monitoring programs such as `ps`, `top`, `iostat`, and `vmstat`. Also, once one has identified a poorly-performing query, further investigation might be needed using PostgreSQL’s `EXPLAIN` command. Section 14.1 discusses `EXPLAIN` and other methods for understanding the behavior of an individual query.

26.1. Standard Unix Tools

On most platforms, PostgreSQL modifies its command title as reported by `ps`, so that individual server processes can readily be identified. A sample display is

```
$ ps auxww | grep ^postgres
postgres 960 0.0 1.1 6104 1480 pts/1 SN 13:17 0:00 postgres -i
postgres 963 0.0 1.1 7084 1472 pts/1 SN 13:17 0:00 postgres: writer process
postgres 965 0.0 1.1 6152 1512 pts/1 SN 13:17 0:00 postgres: stats collector
postgres 998 0.0 2.3 6532 2992 pts/1 SN 13:18 0:00 postgres: tgl runbug 127.0.0.1 idle
postgres 1003 0.0 2.4 6532 3128 pts/1 SN 13:19 0:00 postgres: tgl regression [local] SELECT waiting
postgres 1016 0.1 2.4 6532 3080 pts/1 SN 13:19 0:00 postgres: tgl regression
```

(The appropriate invocation of `ps` varies across different platforms, as do the details of what is shown. This example is from a recent Linux system.) The first process listed here is the master server process. The command arguments shown for it are the same ones given when it was launched. The next two processes are background worker processes automatically launched by the master process. (The “stats collector” process will not be present if you have set the system not to start the statistics collector.) Each of the remaining processes is a server process handling one client connection. Each such process sets its command line display in the form

```
postgres: user database host activity
```

The user, database, and connection source host items remain the same for the life of the client connection, but the activity indicator changes. The activity can be `idle` (i.e., waiting for a client command), `idle in transaction` (waiting for client inside a `BEGIN` block), or a command type name such as `SELECT`. Also, waiting is attached if the server process is presently waiting on a lock held by another server process. In the above example we can infer that process 1003 is waiting for process 1016 to complete its transaction and thereby release some lock or other.

If you have turned off `update_process_title` then the activity indicator is not updated; the process title is set only once when a new process is launched. On some platforms this saves a useful amount of per-command overhead, on others it’s insignificant.

Tip: Solaris requires special handling. You must use `/usr/ucb/ps`, rather than `/bin/ps`. You also must use two `w` flags, not just one. In addition, your original invocation of the `postgres` command must have a shorter `ps` status display than that provided by each server process. If you fail to do all three things, the `ps` output for each server process will be the original `postgres` command line.
26.2. The Statistics Collector

PostgreSQL’s **statistics collector** is a subsystem that supports collection and reporting of information about server activity. Presently, the collector can count accesses to tables and indexes in both disk-block and individual-row terms. It also tracks total numbers of rows in each table, and the last vacuum and analyze times for each table.

PostgreSQL also supports determining the exact command currently being executed by other server processes. This is an independent facility that does not depend on the collector process.

### 26.2.1. Statistics Collection Configuration

Since collection of statistics adds some overhead to query execution, the system can be configured to collect or not collect information. This is controlled by configuration parameters that are normally set in `postgresql.conf`. (See Chapter 18 for details about setting configuration parameters.)

The parameter `track_counts` controls whether information is actually sent to the collector process and thus determines whether any run-time overhead occurs for event counting.

The parameter `track_activities` enables monitoring of the current command being executed by any server process.

Normally these parameters are set in `postgresql.conf` so that they apply to all server processes, but it is possible to turn them on or off in individual sessions using the `SET` command. (To prevent ordinary users from hiding their activity from the administrator, only superusers are allowed to change these parameters with `SET`.)

### 26.2.2. Viewing Collected Statistics

Several predefined views, listed in Table 26-1, are available to show the results of statistics collection. Alternatively, one can build custom views using the underlying statistics functions.

When using the statistics to monitor current activity, it is important to realize that the information does not update instantaneously. Each individual server process transmits new statistical counts to the collector just before going idle; so a query or transaction still in progress does not affect the displayed totals. Also, the collector itself emits a new report at most once per `PGSTAT_STAT_INTERVAL` milliseconds (500 unless altered while building the server). So the displayed information lags behind actual activity. However, current-query information collected by `track_activities` is always up-to-date.

Another important point is that when a server process is asked to display any of these statistics, it first fetches the most recent report emitted by the collector process and then continues to use this snapshot for all statistical views and functions until the end of its current transaction. So the statistics will appear not to change as long as you continue the current transaction. Similarly, information about the current queries of all processes is collected when any such information is first requested within a transaction, and the same information will be displayed throughout the transaction. This is a feature, not a bug, because it allows you to perform several queries on the statistics and correlate the results without worrying that the numbers are changing underneath you. But if you want to see new results with each query, be sure to do the queries outside any transaction block. Alternatively, you can invoke `pg_stat_clear_snapshot()`, which will discard the current transaction’s statistics snapshot (if any). The next use of statistical information will cause a new snapshot to be fetched.

**Table 26-1. Standard Statistics Views**
<table>
<thead>
<tr>
<th>View Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_stat_activity</code></td>
<td>One row per server process, showing database OID, database name, process ID, user OID, user name, current query, query’s waiting status, time at which the current transaction and current query began execution, time at which the process was started, and client’s address and port number. The columns that report data on the current query are available unless the parameter <code>track_activities</code> has been turned off. Furthermore, these columns are only visible if the user examining the view is a superuser or the same as the user owning the process being reported on.</td>
</tr>
<tr>
<td><code>pg_stat_bgwriter</code></td>
<td>One row only, showing cluster-wide statistics from the background writer: number of scheduled checkpoints, requested checkpoints, buffers written by checkpoints and cleaning scans, and the number of times the background writer stopped a cleaning scan because it had written too many buffers. Also includes statistics about the shared buffer pool, including buffers written by backends (that is, not by the background writer) and total buffers allocated.</td>
</tr>
<tr>
<td><code>pg_stat_database</code></td>
<td>One row per database, showing database OID, database name, number of active server processes connected to that database, number of transactions committed and rolled back in that database, total disk blocks read, total buffer hits (i.e., block read requests avoided by finding the block already in buffer cache), number of rows returned, fetched, inserted, updated and deleted.</td>
</tr>
<tr>
<td><code>pg_stat_all_tables</code></td>
<td>For each table in the current database (including TOAST tables), the table OID, schema and table name, number of sequential scans initiated, number of live rows fetched by sequential scans, number of index scans initiated (over all indexes belonging to the table), number of live rows fetched by index scans, numbers of row insertions, updates, and deletions, number of row updates that were HOT (i.e., no separate index update), numbers of live and dead rows, the last time the table was vacuumed manually, the last time it was vacuumed by the autovacuum daemon, the last time it was analyzed manually, and the last time it was analyzed by the autovacuum daemon.</td>
</tr>
<tr>
<td><code>pg_stat_sys_tables</code></td>
<td>Same as <code>pg_stat_all_tables</code>, except that only system tables are shown.</td>
</tr>
</tbody>
</table>
### View Name | Description
--- | ---
pg_stat_user_tables | Same as pg_stat_all_tables, except that only user tables are shown.
pg_stat_all_indexes | For each index in the current database, the table and index OID, schema, table and index name, number of index scans initiated on that index, number of index entries returned by index scans, and number of live table rows fetched by simple index scans using that index.
pg_stat_sys_indexes | Same as pg_stat_all_indexes, except that only indexes on system tables are shown.
pg_stat_user_indexes | Same as pg_stat_all_indexes, except that only indexes on user tables are shown.
pg_statio_all_tables | For each table in the current database (including TOAST tables), the table OID, schema and table name, number of disk blocks read from that table, number of buffer hits, numbers of disk blocks read and buffer hits in all indexes of that table, numbers of disk blocks read and buffer hits from that table’s auxiliary TOAST table (if any), and numbers of disk blocks read and buffer hits for the TOAST table’s index.
pg_statio_sys_tables | Same as pg_statio_all_tables, except that only system tables are shown.
pg_statio_user_tables | Same as pg_statio_all_tables, except that only user tables are shown.
pg_statio_all_indexes | For each index in the current database, the table and index OID, schema, table and index name, numbers of disk blocks read and buffer hits in that index.
pg_statio_sys_indexes | Same as pg_statio_all_indexes, except that only indexes on system tables are shown.
pg_statio_user_indexes | Same as pg_statio_all_indexes, except that only indexes on user tables are shown.
pg_statio_all_sequences | For each sequence object in the current database, the sequence OID, schema and sequence name, numbers of disk blocks read and buffer hits in that sequence.
pg_statio_sys_sequences | Same as pg_statio_all_sequences, except that only indexes on system tables are shown.
pg_statio_user_sequences | Same as pg_statio_all_sequences, except that only indexes on user tables are shown.

The per-index statistics are particularly useful to determine which indexes are being used and how effective they are.

Beginning in PostgreSQL 8.1, indexes can be used either directly or via “bitmap scans”. In a bitmap scan the output of several indexes can be combined via AND or OR rules; so it is difficult to associate
individual heap row fetches with specific indexes when a bitmap scan is used. Therefore, a bitmap scan increments the \texttt{pg\_stat\_all\_indexes.idx\_tup\_read} count(s) for the index(es) it uses, and it increments the \texttt{pg\_stat\_all\_tables.idx\_tup\_fetch} count for the table, but it does not affect \texttt{pg\_stat\_all\_indexes.idx\_tup\_fetch}.

Note: Before PostgreSQL 8.1, the \texttt{idx\_tup\_read} and \texttt{idx\_tup\_fetch} counts were essentially always equal. Now they can be different even without considering bitmap scans, because \texttt{idx\_tup\_read} counts index entries retrieved from the index while \texttt{idx\_tup\_fetch} counts live rows fetched from the table; the latter will be less if any dead or not-yet-committed rows are fetched using the index.

The \texttt{pg\_statio\_views} are primarily useful to determine the effectiveness of the buffer cache. When the number of actual disk reads is much smaller than the number of buffer hits, then the cache is satisfying most read requests without invoking a kernel call. However, these statistics do not give the entire story: due to the way in which PostgreSQL handles disk I/O, data that is not in the PostgreSQL buffer cache might still reside in the kernel’s I/O cache, and might therefore still be fetched without requiring a physical read. Users interested in obtaining more detailed information on PostgreSQL I/O behavior are advised to use the PostgreSQL statistics collector in combination with operating system utilities that allow insight into the kernel’s handling of I/O.

Other ways of looking at the statistics can be set up by writing queries that use the same underlying statistics access functions as these standard views do. These functions are listed in Table 26-2. The per-database access functions take a database OID as argument to identify which database to report on. The per-table and per-index functions take a table or index OID. (Note that only tables and indexes in the current database can be seen with these functions.) The per-server-process access functions take a server process number, which ranges from one to the number of currently active server processes.

<tr>
<td><code>pg_stat_get_buf_written_backend</code></td>
<td><code>bigint</code></td>
<td>The number of buffers written by backends because they needed to allocate a new buffer</td>
</tr>
<tr>
<td><code>pg_stat_get_buf_alloc</code></td>
<td><code>bigint</code></td>
<td>The total number of buffer allocations</td>
</tr>
</tbody>
</table>
Chapter 26. Monitoring Database Activity

<table>
<thead>
<tr>
<th>Function</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_stat_clear_snapshot()</code></td>
<td>void</td>
<td>Discard the current statistics snapshot</td>
</tr>
<tr>
<td><code>pg_stat_reset()</code></td>
<td>void</td>
<td>Reset all statistics counters for the current database to zero (requires superuser privileges)</td>
</tr>
</tbody>
</table>

Note: `blocks_fetched` minus `blocks_hit` gives the number of kernel read() calls issued for the table, index, or database; but the actual number of physical reads is usually lower due to kernel-level buffering.

The function `pg_stat_get_backend_idset` provides a convenient way to generate one row for each active server process. For example, to show the PIDs and current queries of all server processes:

```sql
SELECT pg_stat_get_backend_pid(s.backendid) AS procpid,
       pg_stat_get_backend_activity(s.backendid) AS current_query
FROM (SELECT pg_stat_get_backend_idset() AS backendid) AS s;
```

26.3. Viewing Locks

Another useful tool for monitoring database activity is the `pg_locks` system table. It allows the database administrator to view information about the outstanding locks in the lock manager. For example, this capability can be used to:

- View all the locks currently outstanding, all the locks on relations in a particular database, all the locks on a particular relation, or all the locks held by a particular PostgreSQL session.
- Determine the relation in the current database with the most ungranted locks (which might be a source of contention among database clients).
- Determine the effect of lock contention on overall database performance, as well as the extent to which contention varies with overall database traffic.

Details of the `pg_locks` view appear in Section 44.46. For more information on locking and managing concurrency with PostgreSQL, refer to Chapter 13.

26.4. Dynamic Tracing

PostgreSQL provides facilities to support dynamic tracing of the database server. This allows an external utility to be called at specific points in the code and thereby trace execution. Currently, this facility is primarily intended for use by database developers, as it requires substantial familiarity with the code.

A number of trace points, often called probes, are already inserted into the source code. By default these probes are disabled, and the user needs to explicitly tell the configure script to make the probes available in PostgreSQL.
Currently, only the DTrace utility is supported, which is only available on Solaris Express and Solaris 10+. It is expected that DTrace will be available in the future on FreeBSD and Mac OS X. Supporting other dynamic tracing utilities is theoretically possible by changing the definitions for the `PG_TRACE` macros in `src/include/pg_trace.h`.

### 26.4.1. Compiling for Dynamic Tracing

By default, trace points are disabled, so you will need to explicitly tell the configure script to make the probes available in PostgreSQL. To include DTrace support specify `--enable-dtrace` to configure. See Section 15.5 for further information.

### 26.4.2. Built-in Trace Points

A few standard trace points are provided in the source code (of course, more can be added as needed for a particular problem). These are shown in Table 26-3.

<table>
<thead>
<tr>
<th>Name</th>
<th>Parameters</th>
<th>Overview</th>
</tr>
</thead>
<tbody>
<tr>
<td>transaction__start</td>
<td>(int transactionId)</td>
<td>The start of a new transaction.</td>
</tr>
<tr>
<td>transaction__commit</td>
<td>(int transactionId)</td>
<td>The successful completion of a transaction.</td>
</tr>
<tr>
<td>transaction__abort</td>
<td>(int transactionId)</td>
<td>The unsuccessful completion of a transaction.</td>
</tr>
<tr>
<td>lwlock__acquire</td>
<td>(int lockid, int mode)</td>
<td>An LWLock has been acquired.</td>
</tr>
<tr>
<td>lwlock__release</td>
<td>(int lockid, int mode)</td>
<td>An LWLock has been released.</td>
</tr>
<tr>
<td>lwlock__startwait</td>
<td>(int lockid, int mode)</td>
<td>An LWLock was not immediately available and a backend has begun to wait for the lock to become available.</td>
</tr>
<tr>
<td>lwlock__endwait</td>
<td>(int lockid, int mode)</td>
<td>A backend has been released from its wait for an LWLock.</td>
</tr>
<tr>
<td>lwlock__condacquire</td>
<td>(int lockid, int mode)</td>
<td>An LWLock was successfully acquired when the caller specified no waiting.</td>
</tr>
<tr>
<td>lwlock__condacquire__fail</td>
<td>(int lockid, int mode)</td>
<td>An LWLock was not successfully acquired when the caller specified no waiting.</td>
</tr>
<tr>
<td>lock__startwait</td>
<td>(int locktag_field2, int lockmode)</td>
<td>A request for a heavyweight lock (lmgr lock) has begun to wait because the lock is not available.</td>
</tr>
<tr>
<td>lock__endwait</td>
<td>(int locktag_field2, int lockmode)</td>
<td>A request for a heavyweight lock (lmgr lock) has finished waiting (i.e., has acquired the lock).</td>
</tr>
</tbody>
</table>
26.4.3. Using Trace Points

The example below shows a DTrace script for analyzing transaction counts on the system, as an alternative to snapshotting `pg_stat_database` before and after a performance test:

```d
#!/usr/sbin/dtrace -qs

postgresql$1:::transaction-start
{
    @start["Start"] = count();
    self->ts = timestamp;
}

postgresql$1:::transaction-abort
{
    @abort["Abort"] = count();
}

postgresql$1:::transaction-commit
/self->ts/
{
    @commit["Commit"] = count();
    @time["Total time (ns)"] = sum(timestamp - self->ts);
    self->ts=0;
}
```

Note how the double underline in trace point names needs to be replaced by a hyphen when using D script. When executed, the example D script gives output such as:

```
# ./txn_count.d 'pgrep -n postgres'
^C

Start 71
Commit 70
Total time (ns) 2312105013
```

You should remember that trace programs need to be carefully written and debugged prior to their use, otherwise the trace information collected might be meaningless. In most cases where problems are found it is the instrumentation that is at fault, not the underlying system. When discussing information found using dynamic tracing, be sure to enclose the script used to allow that too to be checked and discussed.

26.4.4. Defining Trace Points

New trace points can be defined within the code wherever the developer desires, though this will require a recompilation.

A trace point can be inserted by using one of the trace macros. These are chosen according to how many variables will be made available for inspection at that trace point. Tracing the occurrence of an event can be achieved with a single line, using just the trace point name, e.g.:

```d
PG_TRACE (my__new__trace__point);
```
More complex trace points can be provided with one or more variables for inspection by the dynamic tracing utility by using the \texttt{PG\_TRACE\_n} macro that corresponds to the number of parameters after the trace point name:

\begin{verbatim}
PG\_TRACE3 (my\_complex\_event, varX, varY, varZ);
\end{verbatim}

The definition of the transaction\_start trace point is shown below:

\begin{verbatim}
static void StartTransaction(void)
{
    ... 
    /*
    * generate a new transaction id
    */
    s->transactionId = GetNewTransactionId(false);
    XactLockTableInsert(s->transactionId);
    PG\_TRACE1(transaction\_start, s->transactionId);
    ... 
}
\end{verbatim}

Note how the transaction ID is made available to the dynamic tracing utility.

The dynamic tracing utility might require you to further define these trace points. For example, DTrace requires you to add new probes to the file \texttt{src/backend/utils/probes.d} as shown here:

\begin{verbatim}
provider postgresql {
    ... 
    probe transaction\_start(int);
    ... 
};
\end{verbatim}

You should take care that the data types specified for the probe arguments match the data types of the variables used in the \texttt{PG\_TRACE} macro. This is not checked at compile time. You can check that your newly added trace point is available by recompiling, then running the new binary, and as root, executing a DTrace command such as:

\begin{verbatim}
dtrace -l -n transaction-start
\end{verbatim}
Chapter 27. Monitoring Disk Usage

This chapter discusses how to monitor the disk usage of a PostgreSQL database system.

27.1. Determining Disk Usage

Each table has a primary heap disk file where most of the data is stored. If the table has any columns with potentially-wide values, there is also a TOAST file associated with the table, which is used to store values too wide to fit comfortably in the main table (see Section 53.2). There will be one index on the TOAST table, if present. There might also be indexes associated with the base table. Each table and index is stored in a separate disk file — possibly more than one file, if the file would exceed one gigabyte. Naming conventions for these files are described in Section 53.1.

You can monitor disk space from three ways: using SQL functions listed in Table 9-54, using VACUUM information, and from the command line using the tools in contrib/oid2name. The SQL functions are the easiest to use and report information about tables, tables with indexes and long value storage (TOAST), databases, and tablespaces.

Using psql on a recently vacuumed or analyzed database, you can issue queries to see the disk usage of any table:

```
SELECT relfilenode, relpages FROM pg_class WHERE relname = 'customer';
```

```
relfilenode | relpages
-------------+----------
16806 | 60
(1 row)
```

Each page is typically 8 kilobytes. (Remember, relpages is only updated by VACUUM, ANALYZE, and a few DDL commands such as CREATE INDEX.) The relfilenode value is of interest if you want to examine the table’s disk file directly.

To show the space used by TOAST tables, use a query like the following:

```
SELECT relname, relpages
FROM pg_class,
     (SELECT reltoastrelid FROM pg_class
      WHERE relname = 'customer') ss
WHERE oid = ss.reltoastrelid
  OR oid = (SELECT reltoastidxid FROM pg_class
            WHERE oid = ss.reltoastrelid)
ORDER BY relname;
```

```
relname        | relpages
---------------+----------
pg_toast_16806 | 0
pg_toast_16806_index | 1
```

You can easily display index sizes, too:

```
SELECT c2.relname, c2.relpages
FROM pg_class c, pg_class c2, pg_index i
WHERE c.relname = 'customer'
  AND c.oid = i.indrelid
```

461
Chapter 27. Monitoring Disk Usage

AND c2.oid = i.indexrelid
ORDER BY c2.relname;

<table>
<thead>
<tr>
<th>relname</th>
<th>relpages</th>
</tr>
</thead>
<tbody>
<tr>
<td>customer_id_indexdex</td>
<td>26</td>
</tr>
</tbody>
</table>

It is easy to find your largest tables and indexes using this information:

```
SELECT relname, relpages FROM pg_class ORDER BY relpages DESC;
```

<table>
<thead>
<tr>
<th>relname</th>
<th>relpages</th>
</tr>
</thead>
<tbody>
<tr>
<td>bigtable</td>
<td>3290</td>
</tr>
<tr>
<td>customer</td>
<td>3144</td>
</tr>
</tbody>
</table>

You can also use `contrib/oid2name` to show disk usage. See `README.oid2name` in that directory for examples. It includes a script that shows disk usage for each database.

27.2. Disk Full Failure

The most important disk monitoring task of a database administrator is to make sure the disk doesn’t grow full. A filled data disk will not result in data corruption, but it might prevent useful activity from occurring. If the disk holding the WAL files grows full, database server panic and consequent shutdown might occur.

If you cannot free up additional space on the disk by deleting other things, you can move some of the database files to other file systems by making use of tablespaces. See Section 20.6 for more information about that.

**Tip:** Some file systems perform badly when they are almost full, so do not wait until the disk is completely full to take action.

If your system supports per-user disk quotas, then the database will naturally be subject to whatever quota is placed on the user the server runs as. Exceeding the quota will have the same bad effects as running out of space entirely.
Chapter 28. Reliability and the Write-Ahead Log

This chapter explains how the Write-Ahead Log is used to obtain efficient, reliable operation.

28.1. Reliability

Reliability is an important property of any serious database system, and PostgreSQL does everything possible to guarantee reliable operation. One aspect of reliable operation is that all data recorded by a committed transaction should be stored in a nonvolatile area that is safe from power loss, operating system failure, and hardware failure (except failure of the nonvolatile area itself, of course). Successfully writing the data to the computer’s permanent storage (disk drive or equivalent) ordinarily meets this requirement. In fact, even if a computer is fatally damaged, if the disk drives survive they can be moved to another computer with similar hardware and all committed transactions will remain intact.

While forcing data periodically to the disk platters might seem like a simple operation, it is not. Because disk drives are dramatically slower than main memory and CPUs, several layers of caching exist between the computer’s main memory and the disk platters. First, there is the operating system’s buffer cache, which caches frequently requested disk blocks and combines disk writes. Fortunately, all operating systems give applications a way to force writes from the buffer cache to disk, and PostgreSQL uses those features. (See the wal_sync_method parameter to adjust how this is done.)

Next, there might be a cache in the disk drive controller; this is particularly common on RAID controller cards. Some of these caches are write-through, meaning writes are passed along to the drive as soon as they arrive. Others are write-back, meaning data is passed on to the drive at some later time. Such caches can be a reliability hazard because the memory in the disk controller cache is volatile, and will lose its contents in a power failure. Better controller cards have battery-backed caches, meaning the card has a battery that maintains power to the cache in case of system power loss. After power is restored the data will be written to the disk drives.

And finally, most disk drives have caches. Some are write-through while some are write-back, and the same concerns about data loss exist for write-back drive caches as exist for disk controller caches. Consumer-grade IDE and SATA drives are particularly likely to have write-back caches that will not survive a power failure. To check write caching on Linux use hdparm -I; it is enabled if there is a * next to Write cache. hdparm -W to turn off write caching. On FreeBSD use atacmd. (For SCSI disks use sdparm to turn off WCE.) On Solaris the disk write cache is controlled by format -e. (The Solaris ZFS file system is safe with disk write-cache enabled because it issues its own disk cache flush commands.) On Windows if wal_sync_method is open_dataasync (the default), write caching is disabled by unchecking My Computer\Open\{select disk drive}\Properties\Hardware\Properties\Policies\Enable write caching on the disk. Also on Windows, fsync and fsync_writethrough never do write caching. The fsync_writethrough option can also be used to disable write caching on MacOS X.

When the operating system sends a write request to the disk hardware, there is little it can do to make sure the data has arrived at a truly non-volatile storage area. Rather, it is the administrator’s responsibility to be sure that all storage components ensure data integrity. Avoid disk controllers that have non-battery-backed write caches. At the drive level, disable write-back caching if the drive cannot guarantee the data will be written before shutdown.

1. http://sg.torque.net/sdparm.html
2. http://www.sun.com/bigadmin/content/submitted/format_utility.jsp
Another risk of data loss is posed by the disk platter write operations themselves. Disk platters are divided into sectors, commonly 512 bytes each. Every physical read or write operation processes a whole sector. When a write request arrives at the drive, it might be for 512 bytes, 1024 bytes, or 8192 bytes, and the process of writing could fail due to power loss at any time, meaning some of the 512-byte sectors were written, and others were not. To guard against such failures, PostgreSQL periodically writes full page images to permanent storage before modifying the actual page on disk. By doing this, during crash recovery PostgreSQL can restore partially-written pages. If you have a battery-backed disk controller or file-system software that prevents partial page writes (e.g., ReiserFS 4), you can turn off this page imaging by using the full_page_writes parameter.

28.2. Write-Ahead Logging (WAL)

Write-Ahead Logging (WAL) is a standard method for ensuring data integrity. A detailed description can be found in most (if not all) books about transaction processing. Briefly, WAL’s central concept is that changes to data files (where tables and indexes reside) must be written only after those changes have been logged, that is, after log records describing the changes have been flushed to permanent storage. If we follow this procedure, we do not need to flush data pages to disk on every transaction commit, because we know that in the event of a crash we will be able to recover the database using the log: any changes that have not been applied to the data pages can be redone from the log records. (This is roll-forward recovery, also known as REDO.)

Using WAL results in a significantly reduced number of disk writes, because only the log file needs to be flushed to disk to guarantee that a transaction is committed, rather than every data file changed by the transaction. The log file is written sequentially, and so the cost of syncing the log is much less than the cost of flushing the data pages. This is especially true for servers handling many small transactions touching different parts of the data store. Furthermore, when the server is processing many small concurrent transactions, one fsync of the log file may suffice to commit many transactions.

WAL also makes it possible to support on-line backup and point-in-time recovery, as described in Section 24.3. By archiving the WAL data we can support reverting to any time instant covered by the available WAL data: we simply install a prior physical backup of the database, and replay the WAL log just as far as the desired time. What’s more, the physical backup doesn’t have to be an instantaneous snapshot of the database state — if it is made over some period of time, then replaying the WAL log for that period will fix any internal inconsistencies.

28.3. Asynchronous Commit

Asynchronous commit is an option that allows transactions to complete more quickly, at the cost that the most recent transactions may be lost if the database should crash. In many applications this is an acceptable trade-off.

As described in the previous section, transaction commit is normally synchronous: the server waits for the transaction’s WAL records to be flushed to permanent storage before returning a success indication to the client. The client is therefore guaranteed that a transaction reported to be committed will be preserved, even in the event of a server crash immediately after. However, for short transactions this delay is a major component of the total transaction time. Selecting asynchronous commit mode means that the server returns success as soon as the transaction is logically completed, before the WAL records it generated have actually made their way to disk. This can provide a significant boost in throughput for small transactions.
Chapter 28. Reliability and the Write-Ahead Log

Asynchronous commit introduces the risk of data loss. There is a short time window between the report of transaction completion to the client and the time that the transaction is truly committed (that is, it is guaranteed not to be lost if the server crashes). Thus asynchronous commit should not be used if the client will take external actions relying on the assumption that the transaction will be remembered. As an example, a bank would certainly not use asynchronous commit for a transaction recording an ATM’s dispensing of cash. But in many scenarios, such as event logging, there is no need for a strong guarantee of this kind.

The risk that is taken by using asynchronous commit is of data loss, not data corruption. If the database should crash, it will recover by replaying WAL up to the last record that was flushed. The database will therefore be restored to a self-consistent state, but any transactions that were not yet flushed to disk will not be reflected in that state. The net effect is therefore loss of the last few transactions. Because the transactions are replayed in commit order, no inconsistency can be introduced — for example, if transaction B made changes relying on the effects of a previous transaction A, it is not possible for A’s effects to be lost while B’s effects are preserved.

The user can select the commit mode of each transaction, so that it is possible to have both synchronous and asynchronous commit transactions running concurrently. This allows flexible trade-offs between performance and certainty of transaction durability. The commit mode is controlled by the user-settable parameter synchronous_commit, which can be changed in any of the ways that a configuration parameter can be set. The mode used for any one transaction depends on the value of synchronous_commit when transaction commit begins.

Certain utility commands, for instance DROP TABLE, are forced to commit synchronously regardless of the setting of synchronous_commit. This is to ensure consistency between the server’s file system and the logical state of the database. The commands supporting two-phase commit, such as PREPARE TRANSACTION, are also always synchronous.

If the database crashes during the risk window between an asynchronous commit and the writing of the transaction’s WAL records, then changes made during that transaction will be lost. The duration of the risk window is limited because a background process (the “WAL writer”) flushes unwritten WAL records to disk every wal_writer_delay milliseconds. The actual maximum duration of the risk window is three times wal_writer_delay because the WAL writer is designed to favor writing whole pages at a time during busy periods.

Caution

An immediate-mode shutdown is equivalent to a server crash, and will therefore cause loss of any unflushed asynchronous commits.

Asynchronous commit provides behavior different from setting fsync = off. fsync is a server-wide setting that will alter the behavior of all transactions. It disables all logic within PostgreSQL that attempts to synchronize writes to different portions of the database, and therefore a system crash (that is, a hardware or operating system crash, not a failure of PostgreSQL itself) could result in arbitrarily bad corruption of the database state. In many scenarios, asynchronous commit provides most of the performance improvement that could be obtained by turning off fsync, but without the risk of data corruption.

commit_delay also sounds very similar to asynchronous commit, but it is actually a synchronous commit method (in fact, commit_delay is ignored during an asynchronous commit). commit_delay causes a delay just before a synchronous commit attempts to flush WAL to disk, in the hope that a single flush executed by one such transaction can also serve other transactions committing at about the same time. Setting commit_delay can only help when there are many concurrently committing transactions, and it is difficult to tune it to a value that actually helps rather than hurting throughput.
28.4. WAL Configuration

There are several WAL-related configuration parameters that affect database performance. This section explains their use. Consult Chapter 18 for general information about setting server configuration parameters.

**Checkpoints** are points in the sequence of transactions at which it is guaranteed that the data files have been updated with all information written before the checkpoint. At checkpoint time, all dirty data pages are flushed to disk and a special checkpoint record is written to the log file. In the event of a crash, the crash recovery procedure looks at the latest checkpoint record to determine the point in the log (known as the redo record) from which it should start the REDO operation. Any changes made to data files before that point are known to be already on disk. Hence, after a checkpoint has been made, any log segments preceding the one containing the redo record are no longer needed and can be recycled or removed. (When WAL archiving is being done, the log segments must be archived before being recycled or removed.)

The server's background writer process will automatically perform a checkpoint every so often. A checkpoint is created every checkpoint_segments log segments, or every checkpoint_timeout seconds, whichever comes first. The default settings are 3 segments and 300 seconds respectively. It is also possible to force a checkpoint by using the SQL command `CHECKPOINT`.

Reducing `checkpoint_segments` and/or `checkpoint_timeout` causes checkpoints to be done more often. This allows faster after-crash recovery (since less work will need to be redone). However, one must balance this against the increased cost of flushing dirty data pages more often. If `full_page_writes` is set (as is the default), there is another factor to consider. To ensure data page consistency, the first modification of a data page after each checkpoint results in logging the entire page content. In that case, a smaller checkpoint interval increases the volume of output to the WAL log, partially negating the goal of using a smaller interval, and in any case causing more disk I/O.

Checkpoints are fairly expensive, first because they require writing out all currently dirty buffers, and second because they result in extra subsequent WAL traffic as discussed above. It is therefore wise to set the checkpointing parameters high enough that checkpoints don’t happen too often. As a simple sanity check on your checkpointing parameters, you can set the `checkpoint_warning` parameter. If checkpoints happen closer together than `checkpoint_warning` seconds, a message will be output to the server log recommending increasing `checkpoint_segments`. Occasional appearance of such a message is not cause for alarm, but if it appears often then the checkpoint control parameters should be increased. Bulk operations such as large `COPY` transfers might cause a number of such warnings to appear if you have not set `checkpoint_segments` high enough.

To avoid flooding the I/O system with a burst of page writes, writing dirty buffers during a checkpoint is spread over a period of time. That period is controlled by `checkpoint_completion_target`, which is given as a fraction of the checkpoint interval. The I/O rate is adjusted so that the checkpoint finishes when the given fraction of `checkpoint_segments` WAL segments have been consumed since checkpoint start, or the given fraction of `checkpoint_timeout` seconds have elapsed, whichever is sooner. With the default value of 0.5, PostgreSQL can be expected to complete each checkpoint in about half the time before the next checkpoint starts. On a system that’s very close to maximum I/O throughput during normal operation, you might want to increase `checkpoint_completion_target` to reduce the I/O load from checkpoints. The disadvantage of this is that prolonging checkpoints affects recovery time, because more WAL segments will need to be kept around for possible use in recovery. Although `checkpoint_completion_target` can be set as high as 1.0, it is best to keep it less than that (perhaps 0.9 at most) since checkpoints include some other activities besides writing dirty buffers. A setting of 1.0 is quite likely to result in checkpoints not being completed on time, which would result in performance loss due to unexpected variation in the number of WAL segments needed.
There will always be at least one WAL segment file, and will normally not be more than \((2 + \text{checkpoint_completion_target}) \times \text{checkpoint_segments} + 1\) files. Each segment file is normally 16 MB (though this size can be altered when building the server). You can use this to estimate space requirements for WAL. Ordinarily, when old log segment files are no longer needed, they are recycled (renamed to become the next segments in the numbered sequence). If, due to a short-term peak of log output rate, there are more than \(3 \times \text{checkpoint_segments} + 1\) segment files, the unneeded segment files will be deleted instead of recycled until the system gets back under this limit.

There are two commonly used internal WAL functions: LogInsert and LogFlush. LogInsert is used to place a new record into the WAL buffers in shared memory. If there is no space for the new record, LogInsert will have to write (move to kernel cache) a few filled WAL buffers. This is undesirable because LogInsert is used on every database low level modification (for example, row insertion) at a time when an exclusive lock is held on affected data pages, so the operation needs to be as fast as possible. What is worse, writing WAL buffers might also force the creation of a new log segment, which takes even more time. Normally, WAL buffers should be written and flushed by a LogFlush request, which is made, for the most part, at transaction commit time to ensure that transaction records are flushed to permanent storage. On systems with high log output, LogFlush requests might not occur often enough to prevent LogInsert from having to do writes. On such systems one should increase the number of WAL buffers by modifying the configuration parameter wal_buffers. The default number of WAL buffers is 8. Increasing this value will correspondingly increase shared memory usage. When full_page_writes is set and the system is very busy, setting this value higher will help smooth response times during the period immediately following each checkpoint.

The commit_delay parameter defines for how many microseconds the server process will sleep after writing a commit record to the log with LogInsert but before performing a LogFlush. This delay allows other server processes to add their commit records to the log so as to have all of them flushed with a single log sync. No sleep will occur if fsync is not enabled, nor if fewer than commit_siblings other sessions are currently in active transactions; this avoids sleeping when it’s unlikely that any other session will commit soon. Note that on most platforms, the resolution of a sleep request is ten milliseconds, so that any nonzero commit_delay setting between 1 and 10000 microseconds would have the same effect. Good values for these parameters are not yet clear; experimentation is encouraged.

The wal_sync_method parameter determines how PostgreSQL will ask the kernel to force WAL updates out to disk. All the options should be the same in terms of reliability, with the exception of fsync_writethrough, which can sometimes force a flush of the disk cache even when other options do not do so. However, it’s quite platform-specific which one will be the fastest; you can test option speeds using the utility src/tools/fsync in the PostgreSQL source tree. Note that this parameter is irrelevant if fsync has been turned off.

Enabling the wal_debug configuration parameter (provided that PostgreSQL has been compiled with support for it) will result in each LogInsert and LogFlush WAL call being logged to the server log. This option might be replaced by a more general mechanism in the future.

### 28.5. WAL Internals

WAL is automatically enabled; no action is required from the administrator except ensuring that the disk-space requirements for the WAL logs are met, and that any necessary tuning is done (see Section 28.4).

WAL logs are stored in the directory `pg_xlog` under the data directory, as a set of segment files, normally each 16 MB in size. Each segment is divided into pages, normally 8 kB each. The log record headers are described in `access/xlog.h`; the record content is dependent on the type of
event that is being logged. Segment files are given ever-increasing numbers as names, starting at 000000010000000000000000. The numbers do not wrap, at present, but it should take a very very long time to exhaust the available stock of numbers.

It is of advantage if the log is located on another disk than the main database files. This can be achieved by moving the directory \texttt{pg\_xlog} to another location (while the server is shut down, of course) and creating a symbolic link from the original location in the main data directory to the new location.

The aim of WAL, to ensure that the log is written before database records are altered, can be subverted by disk drives that falsely report a successful write to the kernel, when in fact they have only cached the data and not yet stored it on the disk. A power failure in such a situation might still lead to irrecoverable data corruption. Administrators should try to ensure that disks holding PostgreSQL’s WAL log files do not make such false reports. (See Section 28.1.)

After a checkpoint has been made and the log flushed, the checkpoint’s position is saved in the file \texttt{pg\_control}. Therefore, when recovery is to be done, the server first reads \texttt{pg\_control} and then the checkpoint record; then it performs the REDO operation by scanning forward from the log position indicated in the checkpoint record. Because the entire content of data pages is saved in the log on the first page modification after a checkpoint, all pages changed since the checkpoint will be restored to a consistent state.

To deal with the case where \texttt{pg\_control} is corrupted, we should support the possibility of scanning existing log segments in reverse order — newest to oldest — in order to find the latest checkpoint. This has not been implemented yet. \texttt{pg\_control} is small enough (less than one disk page) that it is not subject to partial-write problems, and as of this writing there have been no reports of database failures due solely to inability to read \texttt{pg\_control} itself. So while it is theoretically a weak spot, \texttt{pg\_control} does not seem to be a problem in practice.
Chapter 29. Regression Tests

The regression tests are a comprehensive set of tests for the SQL implementation in PostgreSQL. They test standard SQL operations as well as the extended capabilities of PostgreSQL.

29.1. Running the Tests

The regression tests can be run against an already installed and running server, or using a temporary installation within the build tree. Furthermore, there is a “parallel” and a “sequential” mode for running the tests. The sequential method runs each test script in turn, whereas the parallel method starts up multiple server processes to run groups of tests in parallel. Parallel testing gives confidence that interprocess communication and locking are working correctly. For historical reasons, the sequential test is usually run against an existing installation and the parallel method against a temporary installation, but there are no technical reasons for this.

To run the regression tests after building but before installation, type

gmake check

in the top-level directory. (Or you can change to src/test/regress and run the command there.) This will first build several auxiliary files, such as some sample user-defined trigger functions, and then run the test driver script. At the end you should see something like

======================
All 100 tests passed.
======================

or otherwise a note about which tests failed. See Section 29.2 below before assuming that a “failure” represents a serious problem.

Because this test method runs a temporary server, it will not work when you are the root user (since the server will not start as root). If you already did the build as root, you do not have to start all over. Instead, make the regression test directory writable by some other user, log in as that user, and restart the tests. For example

root# chmod -R a+w src/test/regress
root# chmod -R a+w contrib/spi
root# su - joeuser
joeuser$ cd top-level build directory
joeuser$ gmake check

(The only possible “security risk” here is that other users might be able to alter the regression test results behind your back. Use common sense when managing user permissions.)

Alternatively, run the tests after installation.

If you have configured PostgreSQL to install into a location where an older PostgreSQL installation already exists, and you perform gmake check before installing the new version, you might find that the tests fail because the new programs try to use the already-installed shared libraries. (Typical symptoms are complaints about undefined symbols.) If you wish to run the tests before overwriting the old installation, you’ll need to build with configure --disable-rpath. It is not recommended that you use this option for the final installation, however.

The parallel regression test starts quite a few processes under your user ID. Presently, the maximum concurrency is twenty parallel test scripts, which means forty processes: there’s a server process
and a psql process for each test script. So if your system enforces a per-user limit on the number of processes, make sure this limit is at least fifty or so, else you might get random-seeming failures in the parallel test. If you are not in a position to raise the limit, you can cut down the degree of parallelism by setting the `MAX_CONNECTIONS` parameter. For example,

```
gmake MAX_CONNECTIONS=10 check
```

runs no more than ten tests concurrently.

To run the tests after installation (see Chapter 15), initialize a data area and start the server, as explained in Chapter 17, then type

```
gmake installcheck
```

or for a parallel test

```
gmake installcheck-parallel
```

The tests will expect to contact the server at the local host and the default port number, unless directed otherwise by `PGHOST` and `PGPORT` environment variables.

The source distribution also contains regression tests for the optional procedural languages and for some of the `contrib` modules. At present, these tests can be used only against an already-installed server. To run the tests for all procedural languages that have been built and installed, change to the `src/pl` directory of the build tree and type

```
gmake installcheck
```

You can also do this in any of the subdirectories of `src/pl` to run tests for just one procedural language. To run the tests for all `contrib` modules that have them, change to the `contrib` directory of the build tree and type

```
gmake installcheck
```

The `contrib` modules must have been built and installed first. You can also do this in a subdirectory of `contrib` to run the tests for just one module.

### 29.2. Test Evaluation

Some properly installed and fully functional PostgreSQL installations can “fail” some of these regression tests due to platform-specific artifacts such as varying floating-point representation and message wording. The tests are currently evaluated using a simple `diff` comparison against the outputs generated on a reference system, so the results are sensitive to small system differences. When a test is reported as “failed”, always examine the differences between expected and actual results; you might find that the differences are not significant. Nonetheless, we still strive to maintain accurate reference files across all supported platforms, so it can be expected that all tests pass.

The actual outputs of the regression tests are in files in the `src/test/regress/results` directory. The test script uses `diff` to compare each output file against the reference outputs stored in the `src/test/regress/expected` directory. Any differences are saved for your inspection in `src/test/regress/regression.diffs`. (Or you can run `diff` yourself, if you prefer.)

If for some reason a particular platform generates a “failure” for a given test, but inspection of the output convinces you that the result is valid, you can add a new comparison file to silence the failure report in future test runs. See Section 29.3 for details.
Chapter 29. Regression Tests

29.2.1. Error message differences

Some of the regression tests involve intentional invalid input values. Error messages can come from either the PostgreSQL code or from the host platform system routines. In the latter case, the messages can vary between platforms, but should reflect similar information. These differences in messages will result in a “failed” regression test that can be validated by inspection.

29.2.2. Locale differences

If you run the tests against an already-installed server that was initialized with a collation-order locale other than C, then there might be differences due to sort order and follow-up failures. The regression test suite is set up to handle this problem by providing alternative result files that together are known to handle a large number of locales.

29.2.3. Date and time differences

Most of the date and time results are dependent on the time zone environment. The reference files are generated for time zone PST8PDT (Berkeley, California), and there will be apparent failures if the tests are not run with that time zone setting. The regression test driver sets environment variable PGTZ to PST8PDT, which normally ensures proper results.

29.2.4. Floating-point differences

Some of the tests involve computing 64-bit floating-point numbers (double precision) from table columns. Differences in results involving mathematical functions of double precision columns have been observed. The float8 and geometry tests are particularly prone to small differences across platforms, or even with different compiler optimization options. Human eyeball comparison is needed to determine the real significance of these differences which are usually 10 places to the right of the decimal point.

Some systems display minus zero as -0, while others just show 0.

Some systems signal errors from pow() and exp() differently from the mechanism expected by the current PostgreSQL code.

29.2.5. Row ordering differences

You might see differences in which the same rows are output in a different order than what appears in the expected file. In most cases this is not, strictly speaking, a bug. Most of the regression test scripts are not so pedantic as to use an ORDER BY for every single SELECT, and so their result row orderings are not well-defined according to the letter of the SQL specification. In practice, since we are looking at the same queries being executed on the same data by the same software, we usually get the same result ordering on all platforms, and so the lack of ORDER BY isn’t a problem. Some queries do exhibit cross-platform ordering differences, however. When testing against an already-installed server, ordering differences can also be caused by non-C locale settings or non-default parameter settings, such as custom values of work_mem or the planner cost parameters.

Therefore, if you see an ordering difference, it’s not something to worry about, unless the query does have an ORDER BY that your result is violating. But please report it anyway, so that we can add an ORDER BY to that particular query and thereby eliminate the bogus “failure” in future releases.
You might wonder why we don’t order all the regression test queries explicitly to get rid of this issue once and for all. The reason is that that would make the regression tests less useful, not more, since they’d tend to exercise query plan types that produce ordered results to the exclusion of those that don’t.

29.2.6. Insufficient stack depth

If the `errors` test results in a server crash at the `select infinite_recurse()` command, it means that the platform’s limit on process stack size is smaller than the `max_stack_depth` parameter indicates. This can be fixed by running the server under a higher stack size limit (4MB is recommended with the default value of `max_stack_depth`). If you are unable to do that, an alternative is to reduce the value of `max_stack_depth`.

29.2.7. The “random” test

The `random` test script is intended to produce random results. In rare cases, this causes the random regression test to fail. Typing:

```
diff results/random.out expected/random.out
```

should produce only one or a few lines of differences. You need not worry unless the random test fails repeatedly.

29.3. Variant Comparison Files

Since some of the tests inherently produce environment-dependent results, we have provided ways to specify alternative “expected” result files. Each regression test can have several comparison files showing possible results on different platforms. There are two independent mechanisms for determining which comparison file is used for each test.

The first mechanism allows comparison files to be selected for specific platforms. There is a mapping file, `src/test/regress/resultmap`, that defines which comparison file to use for each platform. To eliminate bogus test “failures” for a particular platform, you first choose or make a variant result file, and then add a line to the `resultmap` file.

Each line in the mapping file is of the form

```
testname:output:platformpattern=comparisonfilename
```

The test name is just the name of the particular regression test module. The output value indicates which output file to check. For the standard regression tests, this is always `out`. The value corresponds to the file extension of the output file. The platform pattern is a pattern in the style of the Unix tool `expr` (that is, a regular expression with an implicit ^ anchor at the start). It is matched against the platform name as printed by `config.guess`. The comparison file name is the base name of the substitute result comparison file.

For example: some systems interpret very small floating-point values as zero, rather than reporting an underflow error. This causes a few differences in the `float8` regression test. Therefore, we provide a variant comparison file, `float8-small-is-zero.out`, which includes the results to be expected on these systems. To silence the bogus “failure” message on OpenBSD platforms, `resultmap` includes:
The second selection mechanism for variant comparison files is much more automatic: it simply uses the “best match” among several supplied comparison files. The regression test driver script considers both the standard comparison file for a test, testname.out, and variant files named testname_digit.out (where the digit is any single digit 0-9). If any such file is an exact match, the test is considered to pass; otherwise, the one that generates the shortest diff is used to create the failure report. (If resultmap includes an entry for the particular test, then the base testname is the substitute name given in resultmap.)

For example, for the char test, the comparison file char.out contains results that are expected in the C and POSIX locales, while the file char_1.out contains results sorted as they appear in many other locales.

The best-match mechanism was devised to cope with locale-dependent results, but it can be used in any situation where the test results cannot be predicted easily from the platform name alone. A limitation of this mechanism is that the test driver cannot tell which variant is actually “correct” for the current environment; it will just pick the variant that seems to work best. Therefore it is safest to use this mechanism only for variant results that you are willing to consider equally valid in all contexts.
IV. Client Interfaces

This part describes the client programming interfaces distributed with PostgreSQL. Each of these chapters can be read independently. Note that there are many other programming interfaces for client programs that are distributed separately and contain their own documentation (Appendix G lists some of the more popular ones). Readers of this part should be familiar with using SQL commands to manipulate and query the database (see Part II) and of course with the programming language that the interface uses.
Chapter 30. libpq - C Library

libpq is the C application programmer’s interface to PostgreSQL. libpq is a set of library functions that allow client programs to pass queries to the PostgreSQL backend server and to receive the results of these queries.

libpq is also the underlying engine for several other PostgreSQL application interfaces, including those written for C++, Perl, Python, Tcl and ECPG. So some aspects of libpq’s behavior will be important to you if you use one of those packages. In particular, Section 30.12, Section 30.13 and Section 30.16 describe behavior that is visible to the user of any application that uses libpq.

Some short programs are included at the end of this chapter (Section 30.19) to show how to write programs that use libpq. There are also several complete examples of libpq applications in the directory src/test/examples in the source code distribution.

Client programs that use libpq must include the header file libpq-fe.h and must link with the libpq library.

30.1. Database Connection Control Functions

The following functions deal with making a connection to a PostgreSQL backend server. An application program can have several backend connections open at one time. (One reason to do that is to access more than one database.) Each connection is represented by a PGconn object, which is obtained from the function PQconnectdb or PQsetdbLogin. Note that these functions will always return a non-null object pointer, unless perhaps there is too little memory even to allocate the PGconn object. The PQstatus function should be called to check whether a connection was successfully made before queries are sent via the connection object.

PQconnectdb

Makes a new connection to the database server.

\[
\text{PGconn } \ast \text{PQconnectdb}(\text{const char } \ast \text{conninfo});
\]

This function opens a new database connection using the parameters taken from the string conninfo. Unlike PQsetdbLogin below, the parameter set can be extended without changing the function signature, so use of this function (or its nonblocking analogues PQconnectStart and PQconnectPoll) is preferred for new application programming.

The passed string can be empty to use all default parameters, or it can contain one or more parameter settings separated by whitespace. Each parameter setting is in the form keyword = value. Spaces around the equal sign are optional. To write an empty value or a value containing spaces, surround it with single quotes, e.g., keyword = ‘a value’. Single quotes and backslashes within the value must be escaped with a backslash, i.e., ‘ and \. 

The currently recognized parameter key words are:

host

Name of host to connect to. If this begins with a slash, it specifies Unix-domain communication rather than TCP/IP communication; the value is the name of the directory in which the socket file is stored. The default behavior when host is not specified is to connect to a Unix-domain socket in /tmp (or whatever socket directory was specified when Post-
PostgreSQL was built). On machines without Unix-domain sockets, the default is to connect to localhost.

**hostaddr**

Numeric IP address of host to connect to. This should be in the standard IPv4 address format, e.g., 172.28.40.9. If your machine supports IPv6, you can also use those addresses. TCP/IP communication is always used when a nonempty string is specified for this parameter.

Using `hostaddr` instead of `host` allows the application to avoid a host name look-up, which might be important in applications with time constraints. However, Kerberos and GSSAPI authentication requires the host name. The following therefore applies: If `host` is specified without `hostaddr`, a host name lookup occurs. If `hostaddr` is specified without `host`, the value for `hostaddr` gives the remote address. When Kerberos is used, a reverse name query occurs to obtain the host name for Kerberos. If both `host` and `hostaddr` are specified, the value for `hostaddr` gives the remote address; the value for `host` is ignored, unless Kerberos is used, in which case that value is used for Kerberos authentication. (Note that authentication is likely to fail if `libpq` is passed a host name that is not the name of the machine at `hostaddr`.) Also, `host` rather than `hostaddr` is used to identify the connection in `~/.pgpass` (see Section 30.13).

Without either a host name or host address, `libpq` will connect using a local Unix-domain socket; or on machines without Unix-domain sockets, it will attempt to connect to localhost.

**port**

Port number to connect to at the server host, or socket file name extension for Unix-domain connections.

**dbname**

The database name. Defaults to be the same as the user name.

**user**

PostgreSQL user name to connect as. Defaults to be the same as the operating system name of the user running the application.

**password**

Password to be used if the server demands password authentication.

**connect_timeout**

Maximum wait for connection, in seconds (write as a decimal integer string). Zero or not specified means wait indefinitely. It is not recommended to use a timeout of less than 2 seconds.

**options**

Command-line options to be sent to the server.

**tty**

Ignored (formerly, this specified where to send server debug output).

**sslmode**

This option determines whether or with what priority a SSL TCP/IP connection will be negotiated with the server. There are four modes: `disable` will attempt only an unencrypted SSL connection; `allow` will negotiate, trying first a non-SSL connection, then if that fails,
Chapter 30. libpq - C Library

trying an SSL connection; prefer (the default) will negotiate, trying first an SSL connection, then if that fails, trying a regular non-SSL connection; require will try only an SSL connection. sslmode is ignored for Unix domain socket communication.

If PostgreSQL is compiled without SSL support, using option require will cause an error, while options allow and prefer will be accepted but libpq will not in fact attempt an SSL connection.

requiresl

This option is deprecated in favor of the sslmode setting.

If set to 1, an SSL connection to the server is required (this is equivalent to sslmode require). libpq will then refuse to connect if the server does not accept an SSL connection. If set to 0 (default), libpq will negotiate the connection type with the server (equivalent to sslmode prefer). This option is only available if PostgreSQL is compiled with SSL support.

krbsrvname

Kerberos service name to use when authenticating with Kerberos 5 or GSSAPI. This must match the service name specified in the server configuration for Kerberos authentication to succeed. (See also Section 21.2.5 and Section 21.2.3.)

gsslib

GSS library to use for GSSAPI authentication. Only used on Windows. Set to gssapi to force libpq to use the GSSAPI library for authentication instead of the default SSPI.

service

Service name to use for additional parameters. It specifies a service name in pg_service.conf that holds additional connection parameters. This allows applications to specify only a service name so connection parameters can be centrally maintained. See Section 30.14.

If any parameter is unspecified, then the corresponding environment variable (see Section 30.12) is checked. If the environment variable is not set either, then the indicated built-in defaults are used.

PQsetdbLogin

Makes a new connection to the database server.

PGconn *PQsetdbLogin(const char *pghost,
                        const char *pgport,
                        const char *pgoptions,
                        const char *pgtty,
                        const char *dbName,
                        const char *login,
                        const char *pwd);

This is the predecessor of PQconnectdb with a fixed set of parameters. It has the same functionality except that the missing parameters will always take on default values. Write NULL or an empty string for any one of the fixed parameters that is to be defaulted.

If the dbName contains an = sign, it is taken as a conninfo string in exactly the same way as if it had been passed to PQconnectdb, and the remaining parameters are then applied as above.

PQsetdb

Makes a new connection to the database server.

PGconn *PQsetdb(char *pghost,
Chapter 30. libpq - C Library

This is a macro that calls PQsetdbLogin with null pointers for the login and pwd parameters. It is provided for backward compatibility with very old programs.

PQconnectStart

PQconnectPoll

Make a connection to the database server in a nonblocking manner.

PGconn *PQconnectStart(const char *conninfo);

PostgresPollingStatusType PQconnectPoll(PGconn *conn);

These two functions are used to open a connection to a database server such that your application’s thread of execution is not blocked on remote I/O whilst doing so. The point of this approach is that the waits for I/O to complete can occur in the application’s main loop, rather than down inside PQconnectdb, and so the application can manage this operation in parallel with other activities.

The database connection is made using the parameters taken from the string conninfo, passed to PQconnectStart. This string is in the same format as described above for PQconnectdb.

Neither PQconnectStart nor PQconnectPoll will block, so long as a number of restrictions are met:

- The hostaddr and host parameters are used appropriately to ensure that name and reverse name queries are not made. See the documentation of these parameters under PQconnectdb above for details.

- If you call PQtrace, ensure that the stream object into which you trace will not block.

- You ensure that the socket is in the appropriate state before calling PQconnectPoll, as described below.

To begin a nonblocking connection request, call conn = PQconnectStart("connection_info_string"). If conn is null, then libpq has been unable to allocate a new PGconn structure. Otherwise, a valid PGconn pointer is returned (though not yet representing a valid connection to the database). On return from PQconnectStart, call status = PQstatus(conn). If status equals CONNECTION_BAD, PQconnectStart has failed.

If PQconnectStart succeeds, the next stage is to poll libpq so that it can proceed with the connection sequence. Use PQsocket(conn) to obtain the descriptor of the socket underlying the database connection. Loop thus: If PQconnectPoll(conn) last returned PGRES_POLLING_READING, wait until the socket is ready to read (as indicated by select(), poll(), or similar system function). Then call PQconnectPoll(conn) again. Conversely, if PQconnectPoll(conn) last returned PGRES_POLLING_WRITING, wait until the socket is ready to write, then call PQconnectPoll(conn) again. If you have yet to call PQconnectPoll, i.e., just after the call to PQconnectStart, behave as if it last returned PGRES_POLLING_WRITING. Continue this loop until PQconnectPoll(conn) returns PGRES_POLLING_FAILED, indicating the connection procedure has failed, or PGRES_POLLING_OK, indicating the connection has been successfully made.
At any time during connection, the status of the connection can be checked by calling \texttt{PQstatus}. If this gives \texttt{CONNECTION\_BAD}, then the connection procedure has failed; if it gives \texttt{CONNECTION\_OK}, then the connection is ready. Both of these states are equally detectable from the return value of \texttt{PQconnectPoll}, described above. Other states might also occur during (and only during) an asynchronous connection procedure. These indicate the current stage of the connection procedure and might be useful to provide feedback to the user for example. These statuses are:

\begin{itemize}
  \item \texttt{CONNECTION\_STARTED}
    \begin{itemize}
      \item Waiting for connection to be made.
    \end{itemize}
  \item \texttt{CONNECTION\_MADE}
    \begin{itemize}
      \item Connection OK; waiting to send.
    \end{itemize}
  \item \texttt{CONNECTION\_AWAITING\_RESPONSE}
    \begin{itemize}
      \item Waiting for a response from the server.
    \end{itemize}
  \item \texttt{CONNECTION\_AUTH\_OK}
    \begin{itemize}
      \item Received authentication; waiting for backend start-up to finish.
    \end{itemize}
  \item \texttt{CONNECTION\_SSL\_STARTUP}
    \begin{itemize}
      \item Negotiating SSL encryption.
    \end{itemize}
  \item \texttt{CONNECTION\_SETENV}
    \begin{itemize}
      \item Negotiating environment-driven parameter settings.
    \end{itemize}
\end{itemize}

Note that, although these constants will remain (in order to maintain compatibility), an application should never rely upon these occurring in a particular order, or at all, or on the status always being one of these documented values. An application might do something like this:

\begin{verbatim}
switch(PQstatus(conn))
{
  case CONNECTION\_STARTED:
    feedback = "Connecting...";
    break;

  case CONNECTION\_MADE:
    feedback = "Connected to server...";
    break;

  ...

  default:
    feedback = "Connecting...";
}
\end{verbatim}

The \texttt{connect\_timeout} connection parameter is ignored when using \texttt{PQconnectPoll}; it is the application’s responsibility to decide whether an excessive amount of time has elapsed. Otherwise, \texttt{PQconnectStart} followed by a \texttt{PQconnectPoll} loop is equivalent to \texttt{PQconnectdb}.

Note that if \texttt{PQconnectStart} returns a non-null pointer, you must call \texttt{PQfinish} when you are finished with it, in order to dispose of the structure and any associated memory blocks. This must be done even if the connection attempt fails or is abandoned.
PQconndefaults

Returns the default connection options.

```c
PQconninfoOption *PQconndefaults(void);
```

```c
typedef struct
{
    char *keyword; /* The keyword of the option */
    char *envvar; /* Fallback environment variable name */
    char *compiled; /* Fallback compiled in default value */
    char *val; /* Option’s current value, or NULL */
    char *label; /* Label for field in connect dialog */
    char *dispchar; /* Character to display for this field in a connect dialog. Values are:
                     "" Display entered value as is
                    "*" Password field - hide value
                   "D" Debug option - don’t show by default */
    int dispsize; /* Field size in characters for dialog */
} PQconninfoOption;
```

Returns a connection options array. This can be used to determine all possible `PQconnectdb` options and their current default values. The return value points to an array of `PQconninfoOption` structures, which ends with an entry having a null keyword pointer. The null pointer is returned if memory could not be allocated. Note that the current default values (val fields) will depend on environment variables and other context. Callers must treat the connection options data as read-only.

After processing the options array, free it by passing it to `PQconninfoFree`. If this is not done, a small amount of memory is leaked for each call to `PQconndefaults`.

PQfinish

Closes the connection to the server. Also frees memory used by the `PGconn` object.

```c
void PQfinish(PGconn *conn);
```

Note that even if the server connection attempt fails (as indicated by `PQstatus`), the application should call `PQfinish` to free the memory used by the `PGconn` object. The `PGconn` pointer must not be used again after `PQfinish` has been called.

PQreset

Resets the communication channel to the server.

```c
void PQreset(PGconn *conn);
```

This function will close the connection to the server and attempt to reestablish a new connection to the same server, using all the same parameters previously used. This might be useful for error recovery if a working connection is lost.

PQresetStart
PQresetPoll

Reset the communication channel to the server, in a nonblocking manner.

```c
int PQresetStart(PGconn *conn);
PostgresPollingStatusType PQresetPoll(PGconn *conn);
```
These functions will close the connection to the server and attempt to reestablish a new connection to the same server, using all the same parameters previously used. This can be useful for error recovery if a working connection is lost. They differ from PQreset (above) in that they act in a nonblocking manner. These functions suffer from the same restrictions as PQconnectStart and PQconnectPoll.

To initiate a connection reset, call PQresetStart. If it returns 0, the reset has failed. If it returns 1, poll the reset using PQresetPoll in exactly the same way as you would create the connection using PQconnectPoll.

### 30.2. Connection Status Functions

These functions can be used to interrogate the status of an existing database connection object.

**Tip:** libpq application programmers should be careful to maintain the PGconn abstraction. Use the accessor functions described below to get at the contents of PGconn. Reference to internal PGconn fields using libpq-int.h is not recommended because they are subject to change in the future.

The following functions return parameter values established at connection. These values are fixed for the life of the PGconn object.

- **PQdb**

  Returns the database name of the connection.

  ```c
  char *PQdb(const PGconn *conn);
  ```

- **PQuser**

  Returns the user name of the connection.

  ```c
  char *PQuser(const PGconn *conn);
  ```

- **PQpass**

  Returns the password of the connection.

  ```c
  char *PQpass(const PGconn *conn);
  ```

- **PQhost**

  Returns the server host name of the connection.

  ```c
  char *PQhost(const PGconn *conn);
  ```

- **PQport**

  Returns the port of the connection.

  ```c
  char *PQport(const PGconn *conn);
  ```
Chapter 30. libpq - C Library

PQtty

Returns the debug TTY of the connection. (This is obsolete, since the server no longer pays attention to the TTY setting, but the function remains for backwards compatibility.)

char *PQtty(const PGconn *conn);

PQoptions

Returns the command-line options passed in the connection request.

char *PQoptions(const PGconn *conn);

The following functions return status data that can change as operations are executed on the PGconn object.

PQstatus

Returns the status of the connection.

ConnStatusType PQstatus(const PGconn *conn);

The status can be one of a number of values. However, only two of these are seen outside of an asynchronous connection procedure: CONNECTION_OK and CONNECTION_BAD. A good connection to the database has the status CONNECTION_OK. A failed connection attempt is signaled by status CONNECTION_BAD. Ordinarily, an OK status will remain so until PQfinish, but a communications failure might result in the status changing to CONNECTION_BAD prematurely. In that case the application could try to recover by calling PQreset.

See the entry for PQconnectStart and PQconnectPoll with regards to other status codes that might be seen.

PQtransactionStatus

Returns the current in-transaction status of the server.

PGTransactionStatusType PQtransactionStatus(const PGconn *conn);

The status can be PQTRANS_IDLE (currently idle), PQTRANS_ACTIVE (a command is in progress), PQTRANS_INTRANS (idle, in a valid transaction block), or PQTRANS_INERROR (idle, in a failed transaction block). PQTRANS_UNKNOWN is reported if the connection is bad. PQTRANS_ACTIVE is reported only when a query has been sent to the server and not yet completed.

Caution

PQtransactionStatus will give incorrect results when using a PostgreSQL 7.3 server that has the parameter autocommit set to off. The server-side autocommit feature has been deprecated and does not exist in later server versions.

PQparameterStatus

Looks up a current parameter setting of the server.

const char *PQparameterStatus(const PGconn *conn, const char *paramName);
Certain parameter values are reported by the server automatically at connection startup or whenever their values change. PQparameterStatus can be used to interrogate these settings. It returns the current value of a parameter if known, or NULL if the parameter is not known.

Parameters reported as of the current release include server_version, server_encoding, client_encoding, is_superuser, session_authorization, DateStyle, TimeZone, integer_datetimes, and standard_conforming_strings. (server_encoding, TimeZone, and integer_datetimes were not reported by releases before 8.0; standard_conforming_strings was not reported by releases before 8.1.) Note that server_version, server_encoding and integer_datetimes cannot change after startup.

Pre-3.0-protocol servers do not report parameter settings, but libpq includes logic to obtain values for server_version and client_encoding anyway. Applications are encouraged to use PQparameterStatus rather than ad hoc code to determine these values. (Beware however that on a pre-3.0 connection, changing client_encoding via SET after connection startup will not be reflected by PQparameterStatus.) For server_version, see also PQserverVersion, which returns the information in a numeric form that is much easier to compare against.

If no value for standard_conforming_strings is reported, applications can assume it is off, that is, backslashes are treated as escapes in string literals. Also, the presence of this parameter can be taken as an indication that the escape string syntax (E'...' ) is accepted.

Although the returned pointer is declared const, it in fact points to mutable storage associated with the PGconn structure. It is unwise to assume the pointer will remain valid across queries.

PQprotocolVersion
Interrogates the frontend/backend protocol being used.

    int PQprotocolVersion(const PGconn *conn);

Applications might wish to use this to determine whether certain features are supported. Currently, the possible values are 2 (2.0 protocol), 3 (3.0 protocol), or zero (connection bad). This will not change after connection startup is complete, but it could theoretically change during a connection reset. The 3.0 protocol will normally be used when communicating with PostgreSQL 7.4 or later servers; pre-7.4 servers support only protocol 2.0. (Protocol 1.0 is obsolete and not supported by libpq.)

PQserverVersion
Returns an integer representing the backend version.

    int PQserverVersion(const PGconn *conn);

Applications might use this to determine the version of the database server they are connected to. The number is formed by converting the major, minor, and revision numbers into two-decimal-digit numbers and appending them together. For example, version 8.1.5 will be returned as 80105, and version 8.2 will be returned as 80200 (leading zeroes are not shown). Zero is returned if the connection is bad.

PQerrorMessage
Returns the error message most recently generated by an operation on the connection.

    char *PQerrorMessage(const PGconn *conn);

Nearly all libpq functions will set a message for PQerrorMessage if they fail. Note that by libpq convention, a nonempty PQerrorMessage result will include a trailing newline. The caller should not free the result directly. It will be freed when the associated PGconn handle is passed
to \texttt{PQfinish}. The result string should not be expected to remain the same across operations on the \texttt{PGconn} structure.

\textbf{PQsocket}

Obtains the file descriptor number of the connection socket to the server. A valid descriptor will be greater than or equal to 0; a result of -1 indicates that no server connection is currently open. (This will not change during normal operation, but could change during connection setup or reset.)

\begin{verbatim}
int PQsocket(const PGconn *conn);
\end{verbatim}

\textbf{PQbackendPID}

Returns the process ID (PID) of the backend server process handling this connection.

\begin{verbatim}
int PQbackendPID(const PGconn *conn);
\end{verbatim}

The backend PID is useful for debugging purposes and for comparison to \texttt{NOTIFY} messages (which include the PID of the notifying backend process). Note that the PID belongs to a process executing on the database server host, not the local host!

\textbf{PQconnectionNeedsPassword}

Returns true (1) if the connection authentication method required a password, but none was available. Returns false (0) if not.

\begin{verbatim}
int PQconnectionNeedsPassword(const PGconn *conn);
\end{verbatim}

This function can be applied after a failed connection attempt to decide whether to prompt the user for a password.

\textbf{PQconnectionUsedPassword}

Returns true (1) if the connection authentication method used a caller-supplied password. Returns false (0) if not.

\begin{verbatim}
int PQconnectionUsedPassword(const PGconn *conn);
\end{verbatim}

This function detects whether a password supplied to the connection function was actually used. Passwords obtained from other sources (such as the \texttt{.pgpass} file) are not considered caller-supplied.

\textbf{PQgetssl}

Returns the SSL structure used in the connection, or null if SSL is not in use.

\begin{verbatim}
SSL *PQgetssl(const PGconn *conn);
\end{verbatim}

This structure can be used to verify encryption levels, check server certificates, and more. Refer to the OpenSSL documentation for information about this structure.

You must define \texttt{USE_SSL} in order to get the correct prototype for this function. Doing this will also automatically include \texttt{ssl.h} from OpenSSL.
30.3. Command Execution Functions

Once a connection to a database server has been successfully established, the functions described here are used to perform SQL queries and commands.

30.3.1. Main Functions

PQexec

Submits a command to the server and waits for the result.

```c
PGresult *PQexec(PGconn *conn, const char *command);
```

Returns a `PGresult` pointer or possibly a null pointer. A non-null pointer will generally be returned except in out-of-memory conditions or serious errors such as inability to send the command to the server. If a null pointer is returned, it should be treated like a `PGRES_FATAL_ERROR` result. Use `PQerrorMessage` to get more information about such errors.

It is allowed to include multiple SQL commands (separated by semicolons) in the command string. Multiple queries sent in a single `PQexec` call are processed in a single transaction, unless there are explicit `BEGIN/COMMIT` commands included in the query string to divide it into multiple transactions. Note however that the returned `PGresult` structure describes only the result of the last command executed from the string. Should one of the commands fail, processing of the string stops with it and the returned `PGresult` describes the error condition.

PQexecParams

Submits a command to the server and waits for the result, with the ability to pass parameters separately from the SQL command text.

```c
PGresult *PQexecParams(PGconn *conn,
                         const char *command,
                         int nParams,
                         const Oid *paramTypes,
                         const char * const *paramValues,
                         const int *paramLengths,
                         const int *paramFormats,
                         int resultFormat);
```

`PQexecParams` is like `PQexec`, but offers additional functionality: parameter values can be specified separately from the command string proper, and query results can be requested in either text or binary format. `PQexecParams` is supported only in protocol 3.0 and later connections; it will fail when using protocol 2.0.

The function arguments are:

- `conn`
  
The connection object to send the command through.

- `command`
  
The SQL command string to be executed. If parameters are used, they are referred to in the command string as `$1`, `$2`, etc.
nParams

The number of parameters supplied; it is the length of the arrays paramTypes[],
paramValues[], paramLengths[], and paramFormats[]. (The array pointers can be
NULL when nParams is zero.)

paramTypes[]

Specifies, by OID, the data types to be assigned to the parameter symbols. If paramTypes
is NULL, or any particular element in the array is zero, the server infers a data type for the
parameter symbol in the same way it would do for an untyped literal string.

paramValues[]

Specifies the actual values of the parameters. A null pointer in this array means the corre-
sponding parameter is null; otherwise the pointer points to a zero-terminated text string (for
text format) or binary data in the format expected by the server (for binary format).

paramLengths[]

Specifies the actual data lengths of binary-format parameters. It is ignored for null param-
eters and text-format parameters. The array pointer can be null when there are no binary
parameters.

paramFormats[]

Specifies whether parameters are text (put a zero in the array entry for the correspon-
ding parameter) or binary (put a one in the array entry for the corresponding parameter). If the
array pointer is null then all parameters are presumed to be text strings.

resultFormat

Specify zero to obtain results in text format, or one to obtain results in binary format. (There
is not currently a provision to obtain different result columns in different formats, although
that is possible in the underlying protocol.)

The primary advantage of PQexecParams over PQexec is that parameter values can be separated
from the command string, thus avoiding the need for tedious and error-prone quoting and escaping.

Unlike PQexec, PQexecParams allows at most one SQL command in the given string. (There can be
semicolons in it, but not more than one nonempty command.) This is a limitation of the underlying
protocol, but has some usefulness as an extra defense against SQL-injection attacks.

Tip: Specifying parameter types via OIDs is tedious, particularly if you prefer not to hard-wire
particular OID values into your program. However, you can avoid doing so even in cases where
the server by itself cannot determine the type of the parameter, or chooses a different type than
you want. In the SQL command text, attach an explicit cast to the parameter symbol to show what
data type you will send. For example:

SELECT * FROM mytable WHERE x = $1::bigint;

This forces parameter $1 to be treated as bigint, whereas by default it would be assigned the
same type as x. Forcing the parameter type decision, either this way or by specifying a numeric
type OID, is strongly recommended when sending parameter values in binary format, because
binary format has less redundancy than text format and so there is less chance that the server
will detect a type mismatch mistake for you.
PQprepare

Submits a request to create a prepared statement with the given parameters, and waits for com-
pletion.

PGresult *PQprepare(PGconn *conn,
    const char *stmtName,
    const char *query,
    int nParams,
    const Oid *paramTypes);

PQprepare creates a prepared statement for later execution with PQexecPrepared. This fea-
ture allows commands that will be used repeatedly to be parsed and planned just once, rather than
each time they are executed. PQprepare is supported only in protocol 3.0 and later connections;
it will fail when using protocol 2.0.

The function creates a prepared statement named stmtName from the query string, which must
contain a single SQL command. stmtName can be "" to create an unnamed statement, in which
case any pre-existing unnamed statement is automatically replaced; otherwise it is an error if the
statement name is already defined in the current session. If any parameters are used, they are
referred to in the query as $1, $2, etc. nParams is the number of parameters for which types
are pre-specified in the array paramTypes[]. (The array pointer can be NULL when nParams is
zero.) paramTypes[] specifies, by OID, the data types to be assigned to the parameter symbols.
If paramTypes is NULL, or any particular element in the array is zero, the server assigns a data
type to the parameter symbol in the same way it would do for an untyped literal string. Also, the
query can use parameter symbols with numbers higher than nParams; data types will be inferred
for these symbols as well. (See PQdescribePrepared for a means to find out what data types
were inferred.)

As with PQexec, the result is normally a PGresult object whose contents indicate server-side
success or failure. A null result indicates out-of-memory or inability to send the command at all.
Use PQerrorMessage to get more information about such errors.

 Prepared statements for use with PQexecPrepared can also be created by executing SQL PRE-
pare statements. Also, although there is no libpq function for deleting a prepared statement, the
SQL DEALLOCATE statement can be used for that purpose.

PQexecPrepared

Sends a request to execute a prepared statement with given parameters, and waits for the result.

PGresult *PQexecPrepared(PGconn *conn,
    const char *stmtName,
    int nParams,
    const char * const *paramValues,
    const int *paramLengths,
    const int *paramFormats,
    int resultFormat);

PQexecPrepared is like PQexecParams, but the command to be executed is specified by nam-
ing a previously-prepared statement, instead of giving a query string. This feature allows com-
mands that will be used repeatedly to be parsed and planned just once, rather than each time
they are executed. The statement must have been prepared previously in the current session.
PQexecPrepared is supported only in protocol 3.0 and later connections; it will fail when using
protocol 2.0.

The parameters are identical to PQexecParams, except that the name of a prepared statement is
given instead of a query string, and the paramTypes[] parameter is not present (it is not needed
since the prepared statement’s parameter types were determined when it was created).
**PQdescribePrepared**

Submits a request to obtain information about the specified prepared statement, and waits for completion.

```c
PGresult *PQdescribePrepared(PGconn *conn, const char *stmtName);
```

PQdescribePrepared allows an application to obtain information about a previously prepared statement. PQdescribePrepared is supported only in protocol 3.0 and later connections; it will fail when using protocol 2.0.

stmtName can be "" or NULL to reference the unnamed statement, otherwise it must be the name of an existing prepared statement. On success, a PGresult with status PGRES_COMMAND_OK is returned. The functions PQnparams and PQparamtype can be applied to this PGresult to obtain information about the parameters of the prepared statement, and the functions PQnfields, PQfname, PQftype, etc provide information about the result columns (if any) of the statement.

**PQdescribePortal**

Submits a request to obtain information about the specified portal, and waits for completion.

```c
PGresult *PQdescribePortal(PGconn *conn, const char *portalName);
```

PQdescribePortal allows an application to obtain information about a previously created portal. (libpq does not provide any direct access to portals, but you can use this function to inspect the properties of a cursor created with a DECLARE CURSOR SQL command.) PQdescribePortal is supported only in protocol 3.0 and later connections; it will fail when using protocol 2.0.

portalName can be "" or NULL to reference the unnamed portal, otherwise it must be the name of an existing portal. On success, a PGresult with status PGRES_COMMAND_OK is returned. The functions PQnfields, PQfname, PQftype, etc can be applied to the PGresult to obtain information about the result columns (if any) of the portal.

The PGresult structure encapsulates the result returned by the server. libpq application programmers should be careful to maintain the PGresult abstraction. Use the accessor functions below to get at the contents of PGresult. Avoid directly referencing the fields of the PGresult structure because they are subject to change in the future.

**PQresultStatus**

Returns the result status of the command.

```c
ExecStatusType PQresultStatus(const PGresult *res);
```

PQresultStatus can return one of the following values:

- **PGRES_EMPTY_QUERY**
  The string sent to the server was empty.

- **PGRES_COMMAND_OK**
  Successful completion of a command returning no data.

- **PGRES_TUPLES_OK**
  Successful completion of a command returning data (such as a SELECT or SHOW).

- **PGRES_COPY_OUT**
  Copy Out (from server) data transfer started.
Chapter 30. libpq - C Library

PGRES_COPY_IN

Copy In (to server) data transfer started.

PGRES_BAD_RESPONSE

The server’s response was not understood.

PGRES_NONFATAL_ERROR

A nonfatal error (a notice or warning) occurred.

PGRES_FATAL_ERROR

A fatal error occurred.

If the result status is PGRES_TUPLES_OK, then the functions described below can be used to retrieve the rows returned by the query. Note that a SELECT command that happens to retrieve zero rows still shows PGRES_TUPLES_OK. PGRES_COMMAND_OK is for commands that can never return rows (INSERT, UPDATE, etc.). A response of PGRES_EMPTY_QUERY might indicate a bug in the client software.

A result of status PGRES_NONFATAL_ERROR will never be returned directly by PQexec or other query execution functions; results of this kind are instead passed to the notice processor (see Section 30.11).

PQresStatus

Converts the enumerated type returned by PQresultStatus into a string constant describing the status code. The caller should not free the result.

    char *PQresStatus(ExecStatusType status);

PQresultErrorMessage

Returns the error message associated with the command, or an empty string if there was no error.

    char *PQresultErrorMessage(const PGresult *res);

If there was an error, the returned string will include a trailing newline. The caller should not free the result directly. It will be freed when the associated PGresult handle is passed to PQclear. Immediately following a PQexec or PQgetResult call, PQerrorMessage (on the connection) will return the same string as PQresultErrorMessage (on the result). However, a PGresult will retain its error message until destroyed, whereas the connection’s error message will change when subsequent operations are done. Use PQresultErrorMessage when you want to know the status associated with a particular PGresult; use PQerrorMessage when you want to know the status from the latest operation on the connection.

PQresultErrorField

Returns an individual field of an error report.

    char *PQresultErrorField(const PGresult *res, int fieldcode);

fieldcode is an error field identifier; see the symbols listed below. NULL is returned if the PGresult is not an error or warning result, or does not include the specified field. Field values will normally not include a trailing newline. The caller should not free the result directly. It will be freed when the associated PGresult handle is passed to PQclear.

The following field codes are available:
Chapter 30. libpq - C Library

PG_DIAG_SEVERITY

The severity; the field contents are ERROR, FATAL, or PANIC (in an error message), or WARNING, NOTICE, DEBUG, INFO, or LOG (in a notice message), or a localized translation of one of these. Always present.

PG_DIAG_SQLSTATE

The SQLSTATE code for the error. The SQLSTATE code identifies the type of error that has occurred; it can be used by front-end applications to perform specific operations (such as error handling) in response to a particular database error. For a list of the possible SQLSTATE codes, see Appendix A. This field is not localizable, and is always present.

PG_DIAG_MESSAGE_PRIMARY

The primary human-readable error message (typically one line). Always present.

PG_DIAG_MESSAGE_DETAIL

Detail: an optional secondary error message carrying more detail about the problem. Might run to multiple lines.

PG_DIAG_MESSAGE_HINT

Hint: an optional suggestion what to do about the problem. This is intended to differ from detail in that it offers advice (potentially inappropriate) rather than hard facts. Might run to multiple lines.

PG_DIAG_STATEMENT_POSITION

A string containing a decimal integer indicating an error cursor position as an index into the original statement string. The first character has index 1, and positions are measured in characters not bytes.

PG_DIAG_INTERNAL_POSITION

This is defined the same as the PG_DIAG_STATEMENT_POSITION field, but it is used when the cursor position refers to an internally generated command rather than the one submitted by the client. The PG_DIAG_INTERNAL_QUERY field will always appear when this field appears.

PG_DIAG_INTERNAL_QUERY

The text of a failed internally-generated command. This could be, for example, a SQL query issued by a PL/pgSQL function.

PG_DIAG_CONTEXT

An indication of the context in which the error occurred. Presently this includes a call stack traceback of active procedural language functions and internally-generated queries. The trace is one entry per line, most recent first.

PG_DIAG_SOURCE_FILE

The file name of the source-code location where the error was reported.

PG_DIAG_SOURCE_LINE

The line number of the source-code location where the error was reported.

PG_DIAG_SOURCE_FUNCTION

The name of the source-code function reporting the error.
The client is responsible for formatting displayed information to meet its needs; in particular it should break long lines as needed. Newline characters appearing in the error message fields should be treated as paragraph breaks, not line breaks.

Errors generated internally by libpq will have severity and primary message, but typically no other fields. Errors returned by a pre-3.0-protocol server will include severity and primary message, and sometimes a detail message, but no other fields.

Note that error fields are only available from PGresult objects, not PGconn objects; there is no PQerrorField function.

PQclear

Frees the storage associated with a PGresult. Every command result should be freed via PQclear when it is no longer needed.

void PQclear(PGresult *res);

You can keep a PGresult object around for as long as you need it; it does not go away when you issue a new command, nor even if you close the connection. To get rid of it, you must call PQclear. Failure to do this will result in memory leaks in your application.

PQmakeEmptyPGresult

Constructs an empty PGresult object with the given status.

PGresult *PQmakeEmptyPGresult(PGconn *conn, ExecStatusType status);

This is libpq’s internal function to allocate and initialize an empty PGresult object. This function returns NULL if memory could not be allocated. It is exported because some applications find it useful to generate result objects (particularly objects with error status) themselves. If conn is not null and status indicates an error, the current error message of the specified connection is copied into the PGresult. Note that PQclear should eventually be called on the object, just as with a PGresult returned by libpq itself.

### 30.3.2. Retrieving Query Result Information

These functions are used to extract information from a PGresult object that represents a successful query result (that is, one that has status PGRES_TUPLES_OK). They can also be used to extract information from a successful Describe operation: a Describe’s result has all the same column information that actual execution of the query would provide, but it has zero rows. For objects with other status values, these functions will act as though the result has zero rows and zero columns.

PQntuples

Returns the number of rows (tuples) in the query result. Because it returns an integer result, large result sets might overflow the return value on 32-bit operating systems.

int PQntuples(const PGresult *res);

PQnfields

Returns the number of columns (fields) in each row of the query result.

int PQnfields(const PGresult *res);
Chapter 30. libpq - C Library

PQfname

Returns the column name associated with the given column number. Column numbers start at 0. The caller should not free the result directly. It will be freed when the associated PGresult handle is passed to PQclear.

    char *PQfname(const PGresult *res,
                   int column_number);

NULL is returned if the column number is out of range.

PQfnumber

Returns the column number associated with the given column name.

    int PQfnumber(const PGresult *res,
                   const char *column_name);

-1 is returned if the given name does not match any column.

The given name is treated like an identifier in an SQL command, that is, it is downcased unless double-quoted. For example, given a query result generated from the SQL command:

    SELECT 1 AS FOO, 2 AS "BAR";

we would have the results:

    PQfname(res, 0)  foo
    PQfname(res, 1)  BAR
    PQfnumber(res, "FOO")  0
    PQfnumber(res, "foo")  0
    PQfnumber(res, "BAR") -1
    PQfnumber(res, "\"BAR\"")  1

PQftable

Returns the OID of the table from which the given column was fetched. Column numbers start at 0.

    Oid PQftable(const PGresult *res,
                 int column_number);

InvalidOid is returned if the column number is out of range, or if the specified column is not a simple reference to a table column, or when using pre-3.0 protocol. You can query the system table pg_class to determine exactly which table is referenced.

The type Oid and the constant InvalidOid will be defined when you include the libpq header file. They will both be some integer type.

PQftablecol

Returns the column number (within its table) of the column making up the specified query result column. Query-result column numbers start at 0, but table columns have nonzero numbers.

    int PQftablecol(const PGresult *res,
                    int column_number);

Zero is returned if the column number is out of range, or if the specified column is not a simple reference to a table column, or when using pre-3.0 protocol.
PQfformat

Returns the format code indicating the format of the given column. Column numbers start at 0.

\[
\text{int PQfformat(const PGresult \*res,} \\
\text{int column_number);} \\
\]

Format code zero indicates textual data representation, while format code one indicates binary representation. (Other codes are reserved for future definition.)

PQftype

Returns the data type associated with the given column number. The integer returned is the internal OID number of the type. Column numbers start at 0.

\[
\text{Oid PQftype(const PGresult \*res,} \\
\text{int column_number);} \\
\]

You can query the system table pg_type to obtain the names and properties of the various data types. The OIDs of the built-in data types are defined in the file src/include/catalog/pg_type.h in the source tree.

PQfmod

Returns the type modifier of the column associated with the given column number. Column numbers start at 0.

\[
\text{int PQfmod(const PGresult \*res,} \\
\text{int column_number);} \\
\]

The interpretation of modifier values is type-specific; they typically indicate precision or size limits. The value -1 is used to indicate "no information available". Most data types do not use modifiers, in which case the value is always -1.

PQfsize

Returns the size in bytes of the column associated with the given column number. Column numbers start at 0.

\[
\text{int PQfsize(const PGresult \*res,} \\
\text{int column_number);} \\
\]

PQfsize returns the space allocated for this column in a database row, in other words the size of the server’s internal representation of the data type. (Accordingly, it is not really very useful to clients.) A negative value indicates the data type is variable-length.

PQbinaryTuples

Returns 1 if the PGresult contains binary data and 0 if it contains text data.

\[
\text{int PQbinaryTuples(const PGresult \*res);} \\
\]

This function is deprecated (except for its use in connection with COPY), because it is possible for a single PGresult to contain text data in some columns and binary data in others. PQfformat is preferred. PQbinaryTuples returns 1 only if all columns of the result are binary (format 1).
PQgetvalue

Returns a single field value of one row of a PGresult. Row and column numbers start at 0. The caller should not free the result directly. It will be freed when the associated PGresult handle is passed to PQclear.

```c
char *PQgetvalue(const PGresult *res,
                  int row_number,
                  int column_number);
```

For data in text format, the value returned by PQgetvalue is a null-terminated character string representation of the field value. For data in binary format, the value is in the binary representation determined by the data type's typsend and typreceive functions. (The value is actually followed by a zero byte in this case too, but that is not ordinarily useful, since the value is likely to contain embedded nulls.)

An empty string is returned if the field value is null. See PQgetisnull to distinguish null values from empty-string values.

The pointer returned by PQgetvalue points to storage that is part of the PGresult structure. One should not modify the data it points to, and one must explicitly copy the data into other storage if it is to be used past the lifetime of the PGresult structure itself.

PQgetisnull

Tests a field for a null value. Row and column numbers start at 0.

```c
int PQgetisnull(const PGresult *res,
                 int row_number,
                 int column_number);
```

This function returns 1 if the field is null and 0 if it contains a non-null value. (Note that PQgetvalue will return an empty string, not a null pointer, for a null field.)

PQgetlength

Returns the actual length of a field value in bytes. Row and column numbers start at 0.

```c
int PQgetlength(const PGresult *res,
                 int row_number,
                 int column_number);
```

This is the actual data length for the particular data value, that is, the size of the object pointed to by PQgetvalue. For text data format this is the same as strlen(). For binary format this is essential information. Note that one should not rely on PQfsize to obtain the actual data length.

PQnparams

Returns the number of parameters of a prepared statement.

```c
int PQnparams(const PGresult *res);
```

This function is only useful when inspecting the result of PQdescribePrepared. For other types of queries it will return zero.

PQparamtype

Returns the data type of the indicated statement parameter. Parameter numbers start at 0.

```c
Oid PQparamtype(const PGresult *res, int param_number);
```
Chapter 30. libpq - C Library

This function is only useful when inspecting the result of PQdescribePrepared. For other
types of queries it will return zero.

PQprint

Prints out all the rows and, optionally, the column names to the specified output stream.

```
void PQprint(FILE *fout, /* output stream */
            const PGresult *res,
            const PQprintOpt *po);
```

```c
typedef struct {
    pqbool header;  /* print output field headings and row count */
    pqbool align;   /* fill align the fields */
    pqbool standard; /* old brain dead format */
    pqbool html3;   /* output HTML tables */
    pqbool expanded; /* expand tables */
    pqbool pager;   /* use pager for output if needed */
    char *fieldSep; /* field separator */
    char *tableOpt; /* attributes for HTML table element */
    char *caption;  /* HTML table caption */
    char **fieldName; /* null-terminated array of replacement field names */
} PQprintOpt;
```

This function was formerly used by psql to print query results, but this is no longer the case.
Note that it assumes all the data is in text format.

30.3.3. Retrieving Result Information for Other Commands

These functions are used to extract information from PGresult objects that are not SELECT results.

PQcmdStatus

Returns the command status tag from the SQL command that generated the PGresult.

```
char *PQcmdStatus(PGresult *res);
```

Commonly this is just the name of the command, but it might include additional data such as the
number of rows processed. The caller should not free the result directly. It will be freed when the
associated PGresult handle is passed to PQclear.

PQcmdTuples

Returns the number of rows affected by the SQL command.

```
char *PQcmdTuples(PGresult *res);
```

This function returns a string containing the number of rows affected by the SQL statement
that generated the PGresult. This function can only be used following the execution of an
INSERT, UPDATE, DELETE, MOVE, FETCH, or COPY statement, or an EXECUTE of a prepared
query that contains an INSERT, UPDATE, or DELETE statement. If the command that generated
the PGresult was anything else, PQcmdTuples returns an empty string. The caller should not
free the return value directly. It will be freed when the associated PGresult handle is passed to
PQclear.
Chapter 30. libpq - C Library

**PQoidValue**

Returns the OID of the inserted row, if the SQL command was an `INSERT` that inserted exactly one row into a table that has OIDs, or a `EXECUTE` of a prepared query containing a suitable `INSERT` statement. Otherwise, this function returns `InvalidOid`. This function will also return `InvalidOid` if the table affected by the `INSERT` statement does not contain OIDs.

```c
Oid PQoidValue(const PGresult *res);
```

**PQoidStatus**

Returns a string with the OID of the inserted row, if the SQL command was an `INSERT` that inserted exactly one row, or a `EXECUTE` of a prepared statement consisting of a suitable `INSERT`. (The string will be 0 if the `INSERT` did not insert exactly one row, or if the target table does not have OIDs.) If the command was not an `INSERT`, returns an empty string.

```c
char *PQoidStatus(const PGresult *res);
```

This function is deprecated in favor of `PQoidValue`. It is not thread-safe.

### 30.3.4. Escaping Strings for Inclusion in SQL Commands

`PQescapeStringConn` escapes a string for use within an SQL command. This is useful when inserting data values as literal constants in SQL commands. Certain characters (such as quotes and backslashes) must be escaped to prevent them from being interpreted specially by the SQL parser. `PQescapeStringConn` performs this operation.

**Tip:** It is especially important to do proper escaping when handling strings that were received from an untrustworthy source. Otherwise there is a security risk: you are vulnerable to “SQL injection” attacks wherein unwanted SQL commands are fed to your database.

Note that it is not necessary nor correct to do escaping when a data value is passed as a separate parameter in `PQexecParams` or its sibling routines.

```c
size_t PQescapeStringConn (PGconn *conn, char *to, const char *from, size_t length, int *error);
```

`PQescapeStringConn` writes an escaped version of the `from` string to the `to` buffer, escaping special characters so that they cannot cause any harm, and adding a terminating zero byte. The single quotes that must surround PostgreSQL string literals are not included in the result string; they should be provided in the SQL command that the result is inserted into. The parameter `from` points to the first character of the string that is to be escaped, and the `length` parameter gives the number of bytes in this string. A terminating zero byte is not required, and should not be counted in `length`. (If a terminating zero byte is found before `length` bytes are processed, `PQescapeStringConn` stops at the zero; the behavior is thus rather like `strncpy`) to shall point to a buffer that is able to hold at least one more byte than twice the value of `length`, otherwise the behavior is undefined. Behavior is likewise undefined if the `to` and `from` strings overlap.

If the `error` parameter is not NULL, then `*error` is set to zero on success, nonzero on error. Presently the only possible error conditions involve invalid multibyte encoding in the source string.
The output string is still generated on error, but it can be expected that the server will reject it as malformed. On error, a suitable message is stored in the `conn` object, whether or not `error` is NULL. 
PQescapeStringConn returns the number of bytes written to `to`, not including the terminating zero byte.

```c
size_t PQescapeString (char *to, const char *from, size_t length);
```

PQescapeString is an older, deprecated version of PQescapeStringConn; the difference is that it does not take `conn` or `error` parameters. Because of this, it cannot adjust its behavior depending on the connection properties (such as character encoding) and therefore it might give the wrong results. Also, it has no way to report error conditions.
PQescapeString can be used safely in single-threaded client programs that work with only one PostgreSQL connection at a time (in this case it can find out what it needs to know “behind the scenes”). In other contexts it is a security hazard and should be avoided in favor of PQescapeStringConn.

### 30.3.5. Escaping Binary Strings for Inclusion in SQL Commands

PQescapeByteaConn

Escapes binary data for use within an SQL command with the type `bytea`. As with PQescapeStringConn, this is only used when inserting data directly into an SQL command string.

```c
unsigned char *PQescapeByteaConn (PGconn *conn, const unsigned char *from, size_t from_length, size_t *to_length);
```

Certain byte values must be escaped (but all byte values can be escaped) when used as part of a `bytea` literal in an SQL statement. In general, to escape a byte, it is converted into the three digit octal number equal to the octet value, and preceded by usually two backslashes. The single quote (’) and backslash (\) characters have special alternative escape sequences. See Section 8.4 for more information. PQescapeByteaConn performs this operation, escaping only the minimally required bytes.

The `from` parameter points to the first byte of the string that is to be escaped, and the `from_length` parameter gives the number of bytes in this binary string. (A terminating zero byte is neither necessary nor counted.) The `to_length` parameter points to a variable that will hold the resultant escaped string length. This result string length includes the terminating zero byte of the result.

PQescapeByteaConn returns an escaped version of the `from` parameter binary string in memory allocated with `malloc()`. This memory must be freed using `PQfreemem()` when the result is no longer needed. The return string has all special characters replaced so that they can be properly processed by the PostgreSQL string literal parser, and the `bytea` input function. A terminating zero byte is also added. The single quotes that must surround PostgreSQL string literals are not part of the result string.
On error, a NULL pointer is returned, and a suitable error message is stored in the conn object. Currently, the only possible error is insufficient memory for the result string.

**PQescapeBytea**

*PQescapeBytea is an older, deprecated version of PQescapeByteaConn.*

```c
unsigned char *PQescapeBytea(const unsigned char *from, size_t from_length, size_t *to_length);
```

The only difference from PQescapeByteaConn is that PQescapeBytea does not take a PGconn parameter. Because of this, it cannot adjust its behavior depending on the connection properties (in particular, whether standard-conforming strings are enabled) and therefore it might give the wrong results. Also, it has no way to return an error message on failure.

PQescapeBytea can be used safely in single-threaded client programs that work with only one PostgreSQL connection at a time (in this case it can find out what it needs to know “behind the scenes”). In other contexts it is a security hazard and should be avoided in favor of PQescapeByteaConn.

**PQunescapeBytea**

Converts a string representation of binary data into binary data — the reverse of PQescapeBytea. This is needed when retrieving bytea data in text format, but not when retrieving it in binary format.

```c
unsigned char *PQunescapeBytea(const unsigned char *from, size_t *to_length);
```

The from parameter points to a string such as might be returned by PQgetvalue when applied to a bytea column. PQunescapeBytea converts this string representation into its binary representation. It returns a pointer to a buffer allocated with malloc(), or null on error, and puts the size of the buffer in to_length. The result must be freed using PQfreemem when it is no longer needed.

This conversion is not exactly the inverse of PQescapeBytea, because the string is not expected to be “escaped” when received from PQgetvalue. In particular this means there is no need for string quoting considerations, and so no need for a PGconn parameter.

**PQfreemem**

Frees memory allocated by libpq.

```c
void PQfreemem(void *ptr);
```

Frees memory allocated by libpq, particularly PQescapeByteaConn, PQescapeBytea, PQunescapeBytea, and PQnotifies. It is particularly important that this function, rather than free(), be used on Microsoft Windows. This is because allocating memory in a DLL and releasing it in the application works only if multithreaded/single-threaded, release/debug, and static/dynamic flags are the same for the DLL and the application. On non-Microsoft Windows platforms, this function is the same as the standard library function free().
30.4. Asynchronous Command Processing

The PQexec function is adequate for submitting commands in normal, synchronous applications. It has a couple of deficiencies, however, that can be of importance to some users:

- **PQexec** waits for the command to be completed. The application might have other work to do (such as maintaining a user interface), in which case it won’t want to block waiting for the response.
- Since the execution of the client application is suspended while it waits for the result, it is hard for the application to decide that it would like to try to cancel the ongoing command. (It can be done from a signal handler, but not otherwise.)
- PQexec can return only one PGresult structure. If the submitted command string contains multiple SQL commands, all but the last PGresult are discarded by PQexec.

Applications that do not like these limitations can instead use the underlying functions that PQexec is built from: PQsendQuery and PQgetResult. There are also PQsendQueryParams, PQsendPrepare, PQsendQueryPrepared, PQsendDescribePrepared, and PQsendDescribePortal, which can be used with PQgetResult to duplicate the functionality of PQexecParams, PQprepare, PQexecPrepared, PQdescribePrepared, and PQdescribePortal respectively.

**PQsendQuery**

Submits a command to the server without waiting for the result(s). 1 is returned if the command was successfully dispatched and 0 if not (in which case, use PQerrorMessage to get more information about the failure).

```c
int PQsendQuery(PGconn *conn, const char *command);
```

After successfully calling **PQsendQuery**, call **PQgetResult** one or more times to obtain the results. **PQsendQuery** cannot be called again (on the same connection) until **PQgetResult** has returned a null pointer, indicating that the command is done.

**PQsendQueryParams**

Submits a command and separate parameters to the server without waiting for the result(s).

```c
int PQsendQueryParams(PGconn *conn, const char *command, int nParams, const Oid *paramTypes, const char * const *paramValues, const int *paramLengths, const int *paramFormats, int resultFormat);
```

This is equivalent to **PQsendQuery** except that query parameters can be specified separately from the query string. The function’s parameters are handled identically to **PQexecParams**. Like **PQexecParams**, it will not work on 2.0-protocol connections, and it allows only one command in the query string.

**PQsendPrepare**

Sends a request to create a prepared statement with the given parameters, without waiting for completion.

```c
int PQsendPrepare(PGconn *conn,`
const char *stmtName,
const char *query,
int nParams,
const Oid *paramTypes);  
This is an asynchronous version of PQprepare: it returns 1 if it was able to dispatch the request, and 0 if not. After a successful call, call PQgetResult to determine whether the server successfully created the prepared statement. The function’s parameters are handled identically to PQprepare. Like PQprepare, it will not work on 2.0-protocol connections.

PQsendQueryPrepared
Sends a request to execute a prepared statement with given parameters, without waiting for the result(s).
  
int PQsendQueryPrepared(PGconn *conn,
    const char *stmtName,
    int nParams,
    const char * const *paramValues,
    const int *paramLengths,
    const int *paramFormats,
    int resultFormat);  
This is similar to PQsendQueryParams, but the command to be executed is specified by naming a previously-prepared statement, instead of giving a query string. The function’s parameters are handled identically to PQexecPrepared. Like PQexecPrepared, it will not work on 2.0-protocol connections.

PQsendDescribePrepared
Submits a request to obtain information about the specified prepared statement, without waiting for completion.
  
int PQsendDescribePrepared(PGconn *conn, const char *stmtName);  
This is an asynchronous version of PQdescribePrepared: it returns 1 if it was able to dispatch the request, and 0 if not. After a successful call, call PQgetResult to obtain the results. The function’s parameters are handled identically to PQdescribePrepared. Like PQdescribePrepared, it will not work on 2.0-protocol connections.

PQsendDescribePortal
Submits a request to obtain information about the specified portal, without waiting for completion.
  
int PQsendDescribePortal(PGconn *conn, const char *portalName);  
This is an asynchronous version of PQdescribePortal: it returns 1 if it was able to dispatch the request, and 0 if not. After a successful call, call PQgetResult to obtain the results. The function’s parameters are handled identically to PQdescribePortal. Like PQdescribePortal, it will not work on 2.0-protocol connections.

PQgetResult
Waits for the next result from a prior PQsendQuery, PQsendQueryParams, PQsendPrepare, or PQsendQueryPrepared call, and returns it. A null pointer is returned when the command is complete and there will be no more results.
  
PGresult *PQgetResult(PGconn *conn);
**PQgetResult** must be called repeatedly until it returns a null pointer, indicating that the command is done. (If called when no command is active, **PQgetResult** will just return a null pointer at once.) Each non-null result from **PQgetResult** should be processed using the same **PGresult** accessor functions previously described. Don’t forget to free each result object with **PQclear** when done with it. Note that **PQgetResult** will block only if a command is active and the necessary response data has not yet been read by **PQconsumeInput**.

Using **PQsendQuery** and **PQgetResult** solves one of **PQexec**’s problems: If a command string contains multiple SQL commands, the results of those commands can be obtained individually. (This allows a simple form of overlapped processing, by the way: the client can be handling the results of one command while the server is still working on later queries in the same command string.) However, calling **PQgetResult** will still cause the client to block until the server completes the next SQL command. This can be avoided by proper use of two more functions:

**PQconsumeInput**

If input is available from the server, consume it.

```c
int PQconsumeInput(PGconn *conn);
```

**PQconsumeInput** normally returns 1 indicating “no error”, but returns 0 if there was some kind of trouble (in which case **PQerrorMessage** can be consulted). Note that the result does not say whether any input data was actually collected. After calling **PQconsumeInput**, the application can check **PQisBusy** and/or **PQnotifies** to see if their state has changed.

**PQconsumeInput** can be called even if the application is not prepared to deal with a result or notification just yet. The function will read available data and save it in a buffer, thereby causing a **select()** read-ready indication to go away. The application can thus use **PQconsumeInput** to clear the **select()** condition immediately, and then examine the results at leisure.

**PQisBusy**

Returns 1 if a command is busy, that is, **PQgetResult** would block waiting for input. A 0 return indicates that **PQgetResult** can be called with assurance of not blocking.

```c
int PQisBusy(PGconn *conn);
```

**PQisBusy** will not itself attempt to read data from the server; therefore **PQconsumeInput** must be invoked first, or the busy state will never end.

A typical application using these functions will have a main loop that uses **select()** or **poll()** to wait for all the conditions that it must respond to. One of the conditions will be input available from the server, which in terms of **select()** means readable data on the file descriptor identified by **PQsocket**. When the main loop detects input ready, it should call **PQconsumeInput** to read the input. It can then call **PQisBusy**, followed by **PQgetResult** if **PQisBusy** returns false (0). It can also call **PQnotifies** to detect **NOTIFY** messages (see Section 30.7).

A client that uses **PQsendQuery/PQgetResult** can also attempt to cancel a command that is still being processed by the server; see Section 30.5. But regardless of the return value of **PQcancel**, the application must continue with the normal result-reading sequence using **PQgetResult**. A successful cancellation will simply cause the command to terminate sooner than it would have otherwise.

By using the functions described above, it is possible to avoid blocking while waiting for input from the database server. However, it is still possible that the application will block waiting to send output to the server. This is relatively uncommon but can happen if very long SQL commands or data values are
sent. (It is much more probable if the application sends data via \COPY IN, however.) To prevent this possibility and achieve completely nonblocking database operation, the following additional functions can be used.

**PQsetnonblocking**

Sets the nonblocking status of the connection.

```c
int PQsetnonblocking(PGconn *conn, int arg);
```

Sets the state of the connection to nonblocking if `arg` is 1, or blocking if `arg` is 0. Returns 0 if OK, -1 if error.

In the nonblocking state, calls to `PQsendQuery`, `PQputline`, `PQputnbytes`, and `PQendcopy` will not block but instead return an error if they need to be called again.

Note that `PQexec` does not honor nonblocking mode; if it is called, it will act in blocking fashion anyway.

**PQisnonblocking**

Returns the blocking status of the database connection.

```c
int PQisnonblocking(const PGconn *conn);
```

Returns 1 if the connection is set to nonblocking mode and 0 if blocking.

**PQflush**

Attempts to flush any queued output data to the server. Returns 0 if successful (or if the send queue is empty), -1 if it failed for some reason, or 1 if it was unable to send all the data in the send queue yet (this case can only occur if the connection is nonblocking).

```c
int PQflush(PGconn *conn);
```

After sending any command or data on a nonblocking connection, call `PQflush`. If it returns 1, wait for the socket to be write-ready and call it again; repeat until it returns 0. Once `PQflush` returns 0, wait for the socket to be read-ready and then read the response as described above.

### 30.5. Cancelling Queries in Progress

A client application can request cancellation of a command that is still being processed by the server, using the functions described in this section.

**PQgetCancel**

Creates a data structure containing the information needed to cancel a command issued through a particular database connection.

```c
PGcancel *PQgetCancel(PGconn *conn);
```

`PQgetCancel` creates a `PGcancel` object given a `PGconn` connection object. It will return NULL if the given `conn` is NULL or an invalid connection. The `PGcancel` object is an opaque structure that is not meant to be accessed directly by the application; it can only be passed to `PQcancel` or `PQfreeCancel`. 

---

**503**
Chapter 30. libpq - C Library

PQfreeCancel

Frees a data structure created by PQgetCancel.

```c
void PQfreeCancel(PGcancel *cancel);
```

PQfreeCancel frees a data object previously created by PQgetCancel.

PQcancel

Requests that the server abandon processing of the current command.

```c
int PQcancel(PGcancel *cancel, char *errbuf, int errbufsize);
```

The return value is 1 if the cancel request was successfully dispatched and 0 if not. If not, `errbuf` is filled with an error message explaining why not. `errbuf` must be a char array of size `errbufsize` (the recommended size is 256 bytes).

Successful dispatch is no guarantee that the request will have any effect, however. If the cancellation is effective, the current command will terminate early and return an error result. If the cancellation fails (say, because the server was already done processing the command), then there will be no visible result at all.

PQcancel can safely be invoked from a signal handler, if the `errbuf` is a local variable in the signal handler. The `PGcancel` object is read-only as far as PQcancel is concerned, so it can also be invoked from a thread that is separate from the one manipulating the `PGconn` object.

PQrequestCancel

Requests that the server abandon processing of the current command.

```c
int PQrequestCancel(PGconn *conn);
```

PQrequestCancel is a deprecated variant of PQcancel. It operates directly on the `PGconn` object, and in case of failure stores the error message in the `PGconn` object (whence it can be retrieved by PQerrorMessage). Although the functionality is the same, this approach creates hazards for multiple-thread programs and signal handlers, since it is possible that overwriting the `PGconn`’s error message will mess up the operation currently in progress on the connection.

30.6. The Fast-Path Interface

PostgreSQL provides a fast-path interface to send simple function calls to the server.

**Tip:** This interface is somewhat obsolete, as one can achieve similar performance and greater functionality by setting up a prepared statement to define the function call. Then, executing the statement with binary transmission of parameters and results substitutes for a fast-path function call.

The function PQfn requests execution of a server function via the fast-path interface:

```c
PGresult *PQfn(PGconn *conn,  
   int fnid,  
   int *result_buf,  
   int *result_len,  
   ...)  
```
typedef struct {
    int len;
    int isint;
    union {
        int *ptr;
        int integer;
    } u;
} PQArgBlock;

The fnid argument is the OID of the function to be executed. args and nargs define the parameters to be passed to the function; they must match the declared function argument list. When the isint field of a parameter structure is true, the u.integer value is sent to the server as an integer of the indicated length (this must be 1, 2, or 4 bytes); proper byte-swapping occurs. When isint is false, the indicated number of bytes at *u.ptr are sent with no processing; the data must be in the format expected by the server for binary transmission of the function’s argument data type. result_buf is the buffer in which to place the return value. The caller must have allocated sufficient space to store the return value. (There is no check!) The actual result length will be returned in the integer pointed to by result_len. If a 1, 2, or 4-byte integer result is expected, set result_is_int to 1, otherwise set it to 0. Setting result_is_int to 1 causes libpq to byte-swap the value if necessary, so that it is delivered as a proper int value for the client machine. When result_is_int is 0, the binary-format byte string sent by the server is returned unmodified.

PQfn always returns a valid PGresult pointer. The result status should be checked before the result is used. The caller is responsible for freeing the PGresult with PQclear when it is no longer needed.

Note that it is not possible to handle null arguments, null results, nor set-valued results when using this interface.

30.7. Asynchronous Notification

PostgreSQL offers asynchronous notification via the LISTEN and NOTIFY commands. A client session registers its interest in a particular notification condition with the LISTEN command (and can stop listening with the UNLISTEN command). All sessions listening on a particular condition will be notified asynchronously when a NOTIFY command with that condition name is executed by any session. No additional information is passed from the notifier to the listener. Thus, typically, any actual data that needs to be communicated is transferred through a database table. Commonly, the condition name is the same as the associated table, but it is not necessary for there to be any associated table.

libpq applications submit LISTEN and UNLISTEN commands as ordinary SQL commands. The arrival of NOTIFY messages can subsequently be detected by calling PQnotifies.

The function PQnotifies returns the next notification from a list of unhandled notification messages received from the server. It returns a null pointer if there are no pending notifications. Once a notification is returned from PQnotifies, it is considered handled and will be removed from the list of notifications.

PQnotifies(PQconn *conn);
typedef struct pgNotify {
    char *relname; /* notification condition name */
    int be_pid;    /* process ID of notifying server process */
    char *extra;  /* notification parameter */
} PGnotify;

After processing a PGnotify object returned by PQnotifies, be sure to free it with PQfreemem. It is sufficient to free the PGnotify pointer; the relname and extra fields do not represent separate allocations. (At present, the extra field is unused and will always point to an empty string.)

Example 30-2 gives a sample program that illustrates the use of asynchronous notification.

PQnotifies does not actually read data from the server; it just returns messages previously absorbed by another libpq function. In prior releases of libpq, the only way to ensure timely receipt of NOTIFY messages was to constantly submit commands, even empty ones, and then check PQnotifies after each PQexec. While this still works, it is deprecated as a waste of processing power.

A better way to check for NOTIFY messages when you have no useful commands to execute is to call PQconsumeInput, then check PQnotifies. You can use select() to wait for data to arrive from the server, thereby using no CPU power unless there is something to do. (See PQsocket to obtain the file descriptor number to use with select().) Note that this will work OK whether you submit commands with PQsendQuery/PQgetResult or simply use PQexec. You should, however, remember to check PQnotifies after each PQgetResult or PQexec, to see if any notifications came in during the processing of the command.

### 30.8. Functions Associated with the COPY Command

The COPY command in PostgreSQL has options to read from or write to the network connection used by libpq. The functions described in this section allow applications to take advantage of this capability by supplying or consuming copied data.

The overall process is that the application first issues the SQL COPY command via PQexec or one of the equivalent functions. The response to this (if there is no error in the command) will be a PGresult object bearing a status code of PGRES_COPY_OUT or PGRES_COPY_IN (depending on the specified copy direction). The application should then use the functions of this section to receive or transmit data rows. When the data transfer is complete, another PGresult object is returned to indicate success or failure of the transfer. Its status will be PGRES_COMMAND_OK for success or PGRES_FATAL_ERROR if some problem was encountered. At this point further SQL commands can be issued via PQexec. (It is not possible to execute other SQL commands using the same connection while the COPY operation is in progress.)

If a COPY command is issued via PQexec in a string that could contain additional commands, the application must continue fetching results via PQgetResult after completing the COPY sequence. Only when PQgetResult returns NULL is it certain that the PQexec command string is done and it is safe to issue more commands.

The functions of this section should be executed only after obtaining a result status of PGRES_COPY_OUT or PGRES_COPY_IN from PQexec or PQgetResult.

A PGresult object bearing one of these status values carries some additional data about the COPY operation that is starting. This additional data is available using functions that are also used in connection with query results:
Chapter 30. libpq - C Library

PQnfields

Returns the number of columns (fields) to be copied.

PQbinaryTuples

0 indicates the overall copy format is textual (rows separated by newlines, columns separated by separator characters, etc). 1 indicates the overall copy format is binary. See COPY for more information.

PQfformat

Returns the format code (0 for text, 1 for binary) associated with each column of the copy operation. The per-column format codes will always be zero when the overall copy format is textual, but the binary format can support both text and binary columns. (However, as of the current implementation of COPY, only binary columns appear in a binary copy; so the per-column formats always match the overall format at present.)

Note: These additional data values are only available when using protocol 3.0. When using protocol 2.0, all these functions will return 0.

30.8.1. Functions for Sending COPY Data

These functions are used to send data during COPY FROM STDIN. They will fail if called when the connection is not in COPY_IN state.

PQputCopyData

Sends data to the server during COPY_IN state.

```c
int PQputCopyData(PGconn *conn, const char *buffer, int nbytes);
```

Transmits the COPY data in the specified buffer, of length nbytes, to the server. The result is 1 if the data was sent, zero if it was not sent because the attempt would block (this case is only possible if the connection is in nonblocking mode), or -1 if an error occurred. (Use PQerrorMessage to retrieve details if the return value is -1. If the value is zero, wait for write-ready and try again.)

The application can divide the COPY data stream into buffer loads of any convenient size. Buffer-load boundaries have no semantic significance when sending. The contents of the data stream must match the data format expected by the COPY command; see COPY for details.

PQputCopyEnd

Sends end-of-data indication to the server during COPY_IN state.

```c
int PQputCopyEnd(PGconn *conn, const char *errmsg);
```

Ends the COPY_IN operation successfully if errmsg is NULL. If errmsg is not NULL then the COPY is forced to fail, with the string pointed to by errmsg used as the error message. (One should not assume that this exact error message will come back from the server, however,
as the server might have already failed the COPY for its own reasons. Also note that the option to
force failure does not work when using pre-3.0-protocol connections.)

The result is 1 if the termination data was sent, zero if it was not sent because the attempt would
block (this case is only possible if the connection is in nonblocking mode), or -1 if an error
occurred. (Use PQerrorMessage to retrieve details if the return value is -1. If the value is zero,
wait for write-ready and try again.)

After successfully calling PQputCopyEnd, call PQgetResult to obtain the final result status of
the COPY command. One can wait for this result to be available in the usual way. Then return to
normal operation.

### 30.8.2. Functions for Receiving COPY Data

These functions are used to receive data during COPY TO STDOUT. They will fail if called when the
collection is not in COPY_OUT state.

**PQgetCopyData**

Receives data from the server during COPY_OUT state.

```c
int PQgetCopyData(PGconn *conn,
                 char **buffer,
                 int async);
```

Attempts to obtain another row of data from the server during a COPY. Data is always returned
one row at a time; if only a partial row is available, it is not returned. Successful return of a
data row involves allocating a chunk of memory to hold the data. The buffer parameter must be
non-NULL. *buffer is set to point to the allocated memory, or to NULL in cases where no buffer
is returned. A non-NULL result buffer must be freed using PQfreemem when no longer needed.

When a row is successfully returned, the return value is the number of data bytes in the row (this
will always be greater than zero). The returned string is always null-terminated, though this is
probably only useful for textual COPY. A result of zero indicates that the COPY is still in progress,
but no row is yet available (this is only possible when async is true). A result of -1 indicates that
the COPY is done. A result of -2 indicates that an error occurred (consult PQerrorMessage for
the reason).

When async is true (not zero), PQgetCopyData will not block waiting for input; it will return
zero if the COPY is still in progress but no complete row is available. (In this case wait for read-
ready and then call PQconsumeInput before calling PQgetCopyData again.) When async is
false (zero), PQgetCopyData will block until data is available or the operation completes.

After PQgetCopyData returns -1, call PQgetResult to obtain the final result status of the COPY
command. One can wait for this result to be available in the usual way. Then return to normal
operation.

### 30.8.3. Obsolete Functions for COPY

These functions represent older methods of handling COPY. Although they still work, they are depre-
cated due to poor error handling, inconvenient methods of detecting end-of-data, and lack of support
for binary or nonblocking transfers.
Chapter 30. libpq - C Library

PQgetline

Reads a newline-terminated line of characters (transmitted by the server) into a buffer string of size length.

```c
int PQgetline(PGconn *conn,
               char *buffer,
               int length);
```

This function copies up to length-1 characters into the buffer and converts the terminating newline into a zero byte. PQgetline returns EOF at the end of input, 0 if the entire line has been read, and 1 if the buffer is full but the terminating newline has not yet been read.

Note that the application must check to see if a new line consists of the two characters \., which indicates that the server has finished sending the results of the COPY command. If the application might receive lines that are more than length-1 characters long, care is needed to be sure it recognizes the \. line correctly (and does not, for example, mistake the end of a long data line for a terminator line).

PQgetlineAsync

Reads a row of COPY data (transmitted by the server) into a buffer without blocking.

```c
int PQgetlineAsync(PGconn *conn,
                    char *buffer,
                    int bufsize);
```

This function is similar to PQgetline, but it can be used by applications that must read COPY data asynchronously, that is, without blocking. Having issued the COPY command and gotten a PGRES_COPY_OUT response, the application should call PQconsumeInput and PQgetlineAsync until the end-of-data signal is detected.

Unlike PQgetline, this function takes responsibility for detecting end-of-data.

On each call, PQgetlineAsync will return data if a complete data row is available in libpq’s input buffer. Otherwise, no data is returned until the rest of the row arrives. The function returns -1 if the end-of-copy-data marker has been recognized, or 0 if no data is available, or a positive number giving the number of bytes of data returned. If -1 is returned, the caller must next call PQendcopy, and then return to normal processing.

The data returned will not extend beyond a data-row boundary. If possible a whole row will be returned at one time. But if the buffer offered by the caller is too small to hold a row sent by the server, then a partial data row will be returned. With textual data this can be detected by testing whether the last returned byte is \n or not. (In a binary COPY, actual parsing of the COPY data format will be needed to make the equivalent determination.) The returned string is not null-terminated. (If you want to add a terminating null, be sure to pass a bufsize one smaller than the room actually available.)

PQputline

Sends a null-terminated string to the server. Returns 0 if OK and EOF if unable to send the string.

```c
int PQputline(PGconn *conn,
              const char *string);
```

The COPY data stream sent by a series of calls to PQputline has the same format as that returned by PQgetlineAsync, except that applications are not obliged to send exactly one data row per PQputline call; it is okay to send a partial line or multiple lines per call.
Note: Before PostgreSQL protocol 3.0, it was necessary for the application to explicitly send the two characters \.. as a final line to indicate to the server that it had finished sending `COPY` data. While this still works, it is deprecated and the special meaning of \.. can be expected to be removed in a future release. It is sufficient to call PQendcopy after having sent the actual data.

PQputnbytes
Sends a non-null-terminated string to the server. Returns 0 if OK and EOF if unable to send the string.

```c
int PQputnbytes(PGconn *conn,
    const char *buffer,
    int nbytes);
```

This is exactly like PQputline, except that the data buffer need not be null-terminated since the number of bytes to send is specified directly. Use this procedure when sending binary data.

PQendcopy
Synchronizes with the server.

```c
int PQendcopy(PGconn *conn);
```

This function waits until the server has finished the copying. It should either be issued when the last string has been sent to the server using PQputline or when the last string has been received from the server using PGgetline. It must be issued or the server will get “out of sync” with the client. Upon return from this function, the server is ready to receive the next SQL command. The return value is 0 on successful completion, nonzero otherwise. (Use PQerrorMessage to retrieve details if the return value is nonzero.)

When using PQgetResult, the application should respond to a PGRES_COPY_OUT result by executing PQgetline repeatedly, followed by PQendcopy after the terminator line is seen. It should then return to the PQgetResult loop until PQgetResult returns a null pointer. Similarly a PGRES_COPY_IN result is processed by a series of PQputline calls followed by PQendcopy, then return to the PQgetResult loop. This arrangement will ensure that a COPY command embedded in a series of SQL commands will be executed correctly.

Older applications are likely to submit a COPY via PQexec and assume that the transaction is done after PQendcopy. This will work correctly only if the COPY is the only SQL command in the command string.

### 30.9. Control Functions

These functions control miscellaneous details of libpq’s behavior.

PQclientEncoding
Returns the client encoding.

```c
int PQclientEncoding(const PGconn *conn);
```

Note that it returns the encoding ID, not a symbolic string such as EUC_JP. To convert an encoding ID to an encoding name, you can use:
char *pg_encoding_to_char(int encoding_id);

PQsetClientEncoding

Sets the client encoding.

int PQsetClientEncoding(PGconn *conn, const char *encoding);

cconn is a connection to the server, and encoding is the encoding you want to use. If the function
successfully sets the encoding, it returns 0, otherwise -1. The current encoding for this connection
 can be determined by using PQclientEncoding.

PQsetErrorVerbosity

Determines the verbosity of messages returned by PQerrorMessage and
PQresultErrorMessage.

typedef enum {
  PQERRORS_TERSE,
  PQERRORS_DEFAULT,
  PQERRORS_VERBOSE
} PGVerbosity;

PGVerbosity PQsetErrorVerbosity(PGconn *conn, PGVerbosity verbosity);

PQsetErrorVerbosity sets the verbosity mode, returning the connection’s previous setting.
In TERSE mode, returned messages include severity, primary text, and position only; this will
normally fit on a single line. The default mode produces messages that include the above plus
any detail, hint, or context fields (these might span multiple lines). The VERBOSE mode includes
all available fields. Changing the verbosity does not affect the messages available from already-
existing PGresult objects, only subsequently-created ones.

PQtrace

Enables tracing of the client/server communication to a debugging file stream.

void PQtrace(PGconn *conn, FILE *stream);

Note: On Windows, if the libpq library and an application are compiled with different
flags, this function call will crash the application because the internal representation of
the FILE pointers differ. Specifically, multithreaded/single-threaded, release/debug, and
static/dynamic flags should be the same for the library and all applications using that library.

PQuntrace

Disables tracing started by PQtrace.

void PQuntrace(PGconn *conn);

30.10. Miscellaneous Functions

As always, there are some functions that just don’t fit anywhere.
Chapter 30. libpq - C Library

PQencryptPassword

Prepares the encrypted form of a PostgreSQL password.

```c
char * PQencryptPassword(const char *passwd, const char *user);
```

This function is intended to be used by client applications that wish to send commands like
`ALTER USER joe PASSWORD 'pwd'`. It is good practice not to send the original cleartext password
in such a command, because it might be exposed in command logs, activity displays, and
so on. Instead, use this function to convert the password to encrypted form before it is sent. The
arguments are the cleartext password, and the SQL name of the user it is for. The return value is
a string allocated by `malloc`, or `NULL` if out of memory. The caller can assume the string doesn’t
contain any special characters that would require escaping. Use `PQfreemem` to free the result
when done with it.

30.11. Notice Processing

Notice and warning messages generated by the server are not returned by the query execution func-
tions, since they do not imply failure of the query. Instead they are passed to a notice handling func-
tion, and execution continues normally after the handler returns. The default notice handling function
prints the message on `stderr`, but the application can override this behavior by supplying its own
handling function.

For historical reasons, there are two levels of notice handling, called the notice receiver and notice
processor. The default behavior is for the notice receiver to format the notice and pass a string to the
notice processor for printing. However, an application that chooses to provide its own notice receiver
will typically ignore the notice processor layer and just do all the work in the notice receiver.

The function `PQsetNoticeReceiver` sets or examines the current notice receiver for a connection
object. Similarly, `PQsetNoticeProcessor` sets or examines the current notice processor.

```c
typedef void (*PQnoticeReceiver) (void *arg, const PGresult *res);

PQnoticeReceiver
PQsetNoticeReceiver(PGconn *conn,
                     PQnoticeReceiver proc,
                     void *arg);

datatype void (*PQnoticeProcessor) (void *arg, const char *message);

PQnoticeProcessor
PQsetNoticeProcessor(PGconn *conn,
                     PQnoticeProcessor proc,
                     void *arg);
```

Each of these functions returns the previous notice receiver or processor function pointer, and sets the
new value. If you supply a null function pointer, no action is taken, but the current pointer is returned.

When a notice or warning message is received from the server, or generated internally by libpq, the
notice receiver function is called. It is passed the message in the form of a `PGRES_NONFATAL_ERROR
PGresult`. (This allows the receiver to extract individual fields using `PQresultErrorField`, or the
complete preformatted message using `PQresultErrorMessage`.) The same void pointer passed to
`PQsetNoticeReceiver` is also passed. (This pointer can be used to access application-specific state
if needed.)
The default notice receiver simply extracts the message (using PQresultErrorMessage) and passes it to the notice processor.

The notice processor is responsible for handling a notice or warning message given in text form. It is passed the string text of the message (including a trailing newline), plus a void pointer that is the same one passed to PQsetNoticeProcessor. (This pointer can be used to access application-specific state if needed.)

The default notice processor is simply:

```c
static void
defaultNoticeProcessor(void *arg, const char *message)
{
    fprintf(stderr, "%s", message);
}
```

Once you have set a notice receiver or processor, you should expect that that function could be called as long as either the PGconn object or PGresult objects made from it exist. At creation of a PGresult, the PGconn’s current notice handling pointers are copied into the PGresult for possible use by functions like PQgetvalue.

### 30.12. Environment Variables

The following environment variables can be used to select default connection parameter values, which will be used by PQconnectdb, PQsetdbLogin and PQsetdb if no value is directly specified by the calling code. These are useful to avoid hard-coding database connection information into simple client applications, for example.

- **PGHOST** sets the database server name. If this begins with a slash, it specifies Unix-domain communication rather than TCP/IP communication; the value is then the name of the directory in which the socket file is stored (in a default installation setup this would be /tmp).
- **PGHOSTADDR** specifies the numeric IP address of the database server. This can be set instead of or in addition to PGHOST to avoid DNS lookup overhead. See the documentation of these parameters, under PQconnectdb above, for details on their interaction.
  
  When neither PGHOST nor PGHOSTADDR is set, the default behavior is to connect using a local Unix-domain socket; or on machines without Unix-domain sockets, libpq will attempt to connect to localhost.
- **PGPORT** sets the TCP port number or Unix-domain socket file extension for communicating with the PostgreSQL server.
- **PGDATABASE** sets the PostgreSQL database name.
- **PGUSER** sets the user name used to connect to the database.
- **PGPASSWORD** sets the password used if the server demands password authentication. Use of this environment variable is not recommended for security reasons (some operating systems allow non-root users to see process environment variables via ps); instead consider using the ~/.pgpass file (see Section 30.13).
- **PGPASSFILE** specifies the name of the password file to use for lookups. If not set, it defaults to ~/.pgpass (see Section 30.13).
• **PGSERVICE** sets the service name to be looked up in `pg_service.conf`. This offers a shorthand way of setting all the parameters.

• **PGREALM** sets the Kerberos realm to use with PostgreSQL, if it is different from the local realm. If `PGREALM` is set, libpq applications will attempt authentication with servers for this realm and use separate ticket files to avoid conflicts with local ticket files. This environment variable is only used if Kerberos authentication is selected by the server.

• **PGOPTIONS** sets additional run-time options for the PostgreSQL server.

• **PGSSLMODE** determines whether and with what priority an SSL connection will be negotiated with the server. There are four modes: `disable` will attempt only an unencrypted SSL connection; `allow` will negotiate, trying first a non-SSL connection, then if that fails, trying an SSL connection; `prefer` (the default) will negotiate, trying first an SSL connection, then if that fails, trying a regular non-SSL connection; `require` will try only an SSL connection. If PostgreSQL is compiled without SSL support, using option `require` will cause an error, while options `allow` and `prefer` will be accepted but libpq will not in fact attempt an SSL connection.

• **PGREQUIRESSL** sets whether or not the connection must be made over SSL. If set to “1”, libpq will refuse to connect if the server does not accept an SSL connection (equivalent to `sslmode prefer`). This option is deprecated in favor of the `sslmode` setting, and is only available if PostgreSQL is compiled with SSL support.

• **PGSSLKEY** specifies the hardware token that stores the secret key for the client certificate. The value of this variable should consist of a colon-separated engine name (engines are OpenSSL loadable modules) and an engine-specific key identifier. If this is not set, the secret key must be kept in a file.

• **PGKRBSRVNAME** sets the Kerberos service name to use when authenticating with Kerberos 5 or GSSAPI.

• **PGGSSLIB** sets the GSS library to use for GSSAPI authentication.

• **PGCONNECT_TIMEOUT** sets the maximum number of seconds that libpq will wait when attempting to connect to the PostgreSQL server. If unset or set to zero, libpq will wait indefinitely. It is not recommended to set the timeout to less than 2 seconds.

The following environment variables can be used to specify default behavior for each PostgreSQL session. (See also the `ALTER USER` and `ALTER DATABASE` commands for ways to set default behavior on a per-user or per-database basis.)

• **PGDATESTYLE** sets the default style of date/time representation. (Equivalent to `SET datestyle TO ...`)

• **PGTZ** sets the default time zone. (Equivalent to `SET timezone TO ...`)

• **PGCLIENTENCODING** sets the default client character set encoding. (Equivalent to `SET client_encoding TO ...`)

• **PGGEOQ** sets the default mode for the genetic query optimizer. (Equivalent to `SET geqo TO ...`)

Refer to the SQL command `SET` for information on correct values for these environment variables.

The following environment variables determine internal behavior of libpq; they override compiled-in defaults.

• **PGSYSCONFDIR** sets the directory containing the `pg_service.conf` file.

• **PGLOCALEDIR** sets the directory containing the `locale` files for message internationalization.
30.13. The Password File

The file .pgpass in a user’s home directory or the file referenced by PGPASSFILE can contain passwords to be used if the connection requires a password (and no password has been specified otherwise). On Microsoft Windows the file is named %APPDATA%\postgresql\pgpass.conf (where %APPDATA% refers to the Application Data subdirectory in the user’s profile).

This file should contain lines of the following format:

```
hostname:port:database:username:password
```

Each of the first four fields can be a literal value, or *, which matches anything. The password field from the first line that matches the current connection parameters will be used. (Therefore, put more-specific entries first when you are using wildcards.) If an entry needs to contain : or \, escape this character with \\. A host name of localhost matches both TCP (host name localhost) and Unix domain socket (pghost empty or the default socket directory) connections coming from the local machine.

On Unix systems, the permissions on .pgpass must disallow any access to world or group; achieve this by the command chmod 0600 ~/.pgpass. If the permissions are less strict than this, the file will be ignored. On Microsoft Windows, it is assumed that the file is stored in a directory that is secure, so no special permissions check is made.

30.14. The Connection Service File

The connection service file allows libpq connection parameters to be associated with a single service name. That service name can then be specified by a libpq connection, and the associated settings will be used. This allows connection parameters to be modified without requiring a recompile of the libpq application. The service name can also be specified using the PGSERVICE environment variable.

To use this feature, copy share/pg_service.conf.sample to etc/pg_service.conf and edit the file to add service names and parameters. This file can be used for client-only installs too. The file’s location can also be specified by the PGSYSCONFDIR environment variable.

30.15. LDAP Lookup of Connection Parameters

If libpq has been compiled with LDAP support (option --with-ldap for configure) it is possible to retrieve connection options like host or dbname via LDAP from a central server. The advantage is that if the connection parameters for a database change, the connection information doesn’t have to be updated on all client machines.

LDAP connection parameter lookup uses the connection service file pg_service.conf (see Section 30.14). A line in a pg_service.conf stanza that starts with ldap:// will be recognized as an LDAP URL and an LDAP query will be performed. The result must be a list of keyword = value pairs which will be used to set connection options. The URL must conform to RFC 1959 and be of the form

```
ldap://[hostname[:port]]/search_base?attribute?search_scope?filter
```

where hostname defaults to localhost and port defaults to 389.
Processing of `pg_service.conf` is terminated after a successful LDAP lookup, but is continued if the LDAP server cannot be contacted. This is to provide a fallback with further LDAP URL lines that point to different LDAP servers, classical `keyword = value` pairs, or default connection options. If you would rather get an error message in this case, add a syntactically incorrect line after the LDAP URL.

A sample LDAP entry that has been created with the LDIF file

```plaintext
version:1
dn:cn=mydatabase,dc=mycompany,dc=com
changetype:add
objectclass:top
objectclass:groupOfUniqueNames
cn=mydatabase
uniqueMember:host=dbserver.mycompany.com
uniqueMember:port=5439
uniqueMember:dbname=mydb
uniqueMember:user=mydb_user
uniqueMember:sslmode=require
```

might be queried with the following LDAP URL:

```plaintext
ldap://ldap.mycompany.com/dc=mycompany,dc=com?uniqueMember?one?(cn=mydatabase)
```

You can also mix regular service file entries with LDAP lookups. A complete example for a stanza in `pg_service.conf` would be:

```plaintext
# only host and port are stored in LDAP, specify dbname and user explicitly
[customerdb]
dbname=customer
user=appuser
ldap://ldap.acme.com/cn=dbserver,cn=hosts?pgconnectinfo?base?(objectclass=*),
```

**30.16. SSL Support**

PostgreSQL has native support for using SSL connections to encrypt client/server communications for increased security. See Section 17.8 for details about the server-side SSL functionality.

`libpq` reads the system-wide OpenSSL configuration file. By default, this file is named `openssl.cnf` and is located in the directory reported by `openssl version -d`. This default can be overridden by setting environment variable `OPENSSL_CONF` to the name of the desired configuration file.

To verify the server certificate is trustworthy, place certificates of the certificate authorities (CA) you trust in the file `~/.postgresql/root.crt` in the user’s home directory. (On Microsoft Windows the file is named `%APPDATA%\postgresql\root.crt`.) `libpq` will then verify that the server’s certificate is signed by one of the trusted certificate authorities. The SSL connection will fail if the server does not present a trusted certificate. Certificate Revocation List (CRL) entries are also checked if the file `~/.postgresql/root.crl` exists (`%APPDATA%\postgresql\root.crl` on Microsoft Windows).
Chapter 30. libpq - C Library

If the server requests a trusted client certificate, libpq will send the certificate stored in file
~/.postgresql/postgresql.crt in the user’s home directory. The certificate must be signed
by one of the certificate authorities (CA) trusted by the server. A matching private key file
~/.postgresql/postgresql.key must also be present, unless the secret key for the certificate is
stored in a hardware token, as specified by PGSSLKEY. (On Microsoft Windows these files are named
%APPDATA%\postgresql\postgresql.crt and %APPDATA%\postgresql\postgresql.key.)
The private key file must not be world-readable.

If the environment variable PGSSLKEY is set, its value should consist of a colon-separated engine
name and key identifier. In this case, libpq will load the specified engine, i.e. the OpenSSL module
which supports special hardware, and reference the key with the specified identifier. Identifiers are
eengine-specific. Typically, cryptography hardware tokens do not reveal secret keys to the application.
Instead, applications delegate all cryptography operations which require the secret key to the hardware
token.

If you are using SSL inside your application (in addition to inside libpq), you can use
PQinitSSL(int) to tell libpq that the SSL library has already been initialized by your application.

Table 30-1. Libpq/Client SSL File Usage

<table>
<thead>
<tr>
<th>File</th>
<th>Contents</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>~/.postgresql/postgresql.crt</td>
<td>client certificate</td>
<td>requested by server</td>
</tr>
<tr>
<td>~/.postgresql/postgresql.key</td>
<td>client private key</td>
<td>proves client certificate sent by owner; does not indicate certificate owner is trustworthy</td>
</tr>
<tr>
<td>~/.postgresql/root.crt</td>
<td>trusted certificate authorities</td>
<td>checks server certificate is signed by a trusted certificate authority</td>
</tr>
<tr>
<td>~/.postgresql/root.crl</td>
<td>certificates revoked by</td>
<td>server certificate must not be on certificate authorities</td>
</tr>
</tbody>
</table>

30.17. Behavior in Threaded Programs

libpq is reentrant and thread-safe if the configure command-line option
--enable-thread-safety was used when the PostgreSQL distribution was built. In addition, you
might need to use additional compiler command-line options when you compile your application
code. Refer to your system’s documentation for information about how to build thread-enabled
applications, or look in src/Makefile.global for PTHREAD_CFLAGS and PTHREAD_LIBS. This
function allows the querying of libpq’s thread-safe status:

PQisthreadsafe

Returns the thread safety status of the libpq library.

int PQisthreadsafe();

Returns 1 if the libpq is thread-safe and 0 if it is not.

One thread restriction is that no two threads attempt to manipulate the same PGconn object at the
same time. In particular, you cannot issue concurrent commands from different threads through the
same connection object. (If you need to run concurrent commands, use multiple connections.)

PGresult objects are read-only after creation, and so can be passed around freely between threads.

The deprecated functions PQrequestCancel and PQoidStatus are not thread-safe and should not be used in multithread programs. PQrequestCancel can be replaced by PQcancel. PQoidStatus can be replaced by PQoidValue.

If you are using Kerberos inside your application (in addition to inside libpq), you will need to do locking around Kerberos calls because Kerberos functions are not thread-safe. See function PQregisterThreadLock in the libpq source code for a way to do cooperative locking between libpq and your application.

If you experience problems with threaded applications, run the program in src/tools/thread to see if your platform has thread-unsafe functions. This program is run by configure, but for binary distributions your library might not match the library used to build the binaries.

### 30.18. Building libpq Programs

To build (i.e., compile and link) a program using libpq you need to do all of the following things:

- Include the libpq-fe.h header file:

  ```
  #include <libpq-fe.h>
  ```

  If you failed to do that then you will normally get error messages from your compiler similar to

  ```
  foo.c:34: 'PGconn' undeclared (first use in this function)
  foo.c:35: 'PGresult' undeclared (first use in this function)
  foo.c:54: 'CONNECTION_BAD' undeclared (first use in this function)
  foo.c:68: 'PGRES_COMMAND_OK' undeclared (first use in this function)
  foo.c:95: 'PGRES_TUPLES_OK' undeclared (first use in this function)
  ```

- Point your compiler to the directory where the PostgreSQL header files were installed, by supplying the `-I` directory option to your compiler. (In some cases the compiler will look into the directory in question by default, so you can omit this option.) For instance, your compile command line could look like:

  ```
  cc -c -I/usr/local/pgsql/include testprog.c
  ```

  If you are using makefiles then add the option to the `CPPFLAGS` variable:

  ```
  CPPFLAGS += -I/usr/local/pgsql/include
  ```

  If there is any chance that your program might be compiled by other users then you should not hardcode the directory location like that. Instead, you can run the utility `pg_config` to find out where the header files are on the local system:

  ```
  $ pg_config --includedir /usr/local/include
  ```

  Failure to specify the correct option to the compiler will result in an error message such as

  ```
  testlibpq.c:8:22: libpq-fe.h: No such file or directory
  ```

- When linking the final program, specify the option `-lpq` so that the libpq library gets pulled in, as well as the option `-L` directory to point the compiler to the directory where the libpq library resides. (Again, the compiler will search some directories by default.) For maximum portability, put the `-L` option before the `-lpq` option. For example:
Chapter 30. libpq - C Library

cc -o testprog testprog1.o testprog2.o -L/usr/local/pgsql/lib -lpq

You can find out the library directory using `pg_config` as well:

$ pg_config --libdir
/usr/local/pgsql/lib

Error messages that point to problems in this area could look like the following.

testlibpq.o: In function ‘main’:
testlibpq.o(.text+0x60): undefined reference to ‘PQsetdbLogin’
testlibpq.o(.text+0x71): undefined reference to ‘PQstatus’
testlibpq.o(.text+0xa4): undefined reference to ‘PQerrorMessage’
This means you forgot `-lpq`.
/usr/bin/ld: cannot find `-lpq`
This means you forgot the `-L` option or did not specify the right directory.

30.19. Example Programs

These examples and others can be found in the directory `src/test/examples` in the source code distribution.

Example 30-1. libpq Example Program 1

```c
/*
 * testlibpq.c
 *
 * Test the C version of libpq, the PostgreSQL frontend library.
 */
#include <stdio.h>
#include <stdlib.h>
#include "libpq-fe.h"

static void
exit_nicely(PGconn *conn)
{
    PQfinish(conn);
    exit(1);
}

int
main(int argc, char **argv)
{
    const char *conninfo;
    PGconn *conn;
    PGresult *res;
    int nFields;
    int i,
     j;

    /*
     * If the user supplies a parameter on the command line, use it as the
     * conninfo string; otherwise default to setting dbname=postgres and using
     * environment variables or defaults for all other connection parameters.
     */
```
if (argc > 1)
    conninfo = argv[1];
else
    conninfo = "dbname = postgres";

/* Make a connection to the database */
conn = PQconnectdb(conninfo);

/* Check to see that the backend connection was successfully made */
if (PQstatus(conn) != CONNECTION_OK)
{
    fprintf(stderr, "Connection to database failed: %s",
            PQerrorMessage(conn));
    exit_nicely(conn);
}

/* Our test case here involves using a cursor, for which we must be inside
 * a transaction block. We could do the whole thing with a single
 * PQexec() of "select * from pg_database", but that's too trivial to make
 * a good example.
 */

/* Start a transaction block */
res = PQexec(conn, "BEGIN");
if (PQresultStatus(res) != PGRES_COMMAND_OK)
{
    fprintf(stderr, "BEGIN command failed: %s", PQerrorMessage(conn));
    PQclear(res);
    exit_nicely(conn);
}

/* Should PQclear PGresult whenever it is no longer needed to avoid memory
 * leaks
 */
PQclear(res);

/* Fetch rows from pg_database, the system catalog of databases */
res = PQexec(conn, "DECLARE myportal CURSOR FOR select * from pg_database");
if (PQresultStatus(res) != PGRES_COMMAND_OK)
{
    fprintf(stderr, "DECLARE CURSOR failed: %s", PQerrorMessage(conn));
    PQclear(res);
    exit_nicely(conn);
}
PQclear(res);

res = PQexec(conn, "FETCH ALL in myportal");
if (PQresultStatus(res) != PGRES_TUPLES_OK)
{
    fprintf(stderr, "FETCH ALL failed: %s", PQerrorMessage(conn));
    PQclear(res);
    exit_nicely(conn);
}
Chapter 30. libpq - C Library

Example 30-2. libpq Example Program 2

```c
/*
 * testlibpq2.c
 * Test of the asynchronous notification interface
 *
 * Start this program, then from psql in another window do
 * NOTIFY TBL2;
 * Repeat four times to get this program to exit.
 *
 * Or, if you want to get fancy, try this:
 * populate a database with the following commands
 * (provided in src/test/examples/testlibpq2.sql):
 *  * CREATE TABLE TBL1 (i int4);
 *  * CREATE TABLE TBL2 (i int4);
 *  * CREATE RULE r1 AS ON INSERT TO TBL1 DO
 *  * (INSERT INTO TBL2 VALUES (new.i); NOTIFY TBL2);
 *  *
 *  * and do this four times:
 *  *
 *  * INSERT INTO TBL1 VALUES (10);
 *  */

#include <stdio.h>
```
#include <stdlib.h>
#include <string.h>
#include <errno.h>
#include <sys/time.h>
#include "libpq-fe.h"

static void
exit_nicely(PGconn *conn)
{
  PQfinish(conn);
  exit(1);
}

int
main(int argc, char **argv)
{
  const char *conninfo;
  PGconn  *conn;
  PGresult *res;
  PGnotify *notify;
  int nnotifies;

  /*
   * If the user supplies a parameter on the command line, use it as the
   * conninfo string; otherwise default to setting dbname=postgres and using
   * environment variables or defaults for all other connection parameters.
   */
  if (argc > 1)
    conninfo = argv[1];
  else
    conninfo = "dbname = postgres";

  /* Make a connection to the database */
  conn = PQconnectdb(conninfo);

  /* Check to see that the backend connection was successfully made */
  if (PQstatus(conn) != CONNECTION_OK)
    {
      fprintf(stderr, "Connection to database failed: %s", 
PQerrorMessage(conn));
      exit_nicely(conn);
    }

  /*
   * Issue LISTEN command to enable notifications from the rule’s NOTIFY.
   */
  res = PQexec(conn, "LISTEN TBL2");
  if (PQresultStatus(res) != PGRES_COMMAND_OK)
    {
      fprintf(stderr, "LISTEN command failed: %s", PQerrorMessage(conn));
      PQclear(res);
      exit_nicely(conn);
    }

  /*
   * should PQclear PGresult whenever it is no longer needed to avoid memory
   * leaks
   */
PQclear(res);

/* Quit after four notifies are received. */
nnotifies = 0;
while (nnotifies < 4)
{
    /*
     * Sleep until something happens on the connection. We use select(2)
     * to wait for input, but you could also use poll() or similar
     * facilities.
     */
    int sock;
    FD_ZERO(&input_mask);
    sock = PQsocket(conn);
    if (sock < 0)
        /* shouldn’t happen */
        break;
    FD_SET(sock, &input_mask);
    if (select(sock + 1, &input_mask, NULL, NULL, NULL) < 0)
    {
        fprintf(stderr, "select() failed: %s\n", strerror(errno));
        exit_nicely(conn);
    }
    /* Now check for input */
    PQconsumeInput(conn);
    while ((notify = PQnotifies(conn)) != NULL)
    {
        fprintf(stderr,
                "ASYNC NOTIFY of ‘%s’ received from backend pid %d\n",
                notify->relname, notify->be_pid);
        PQfreemem(notify);
        nnotifies++;
    }
    fprintf(stderr, "Done.\n");
}

Example 30-3. libpq Example Program 3

/*
 * testlibpq3.c
 * Test out-of-line parameters and binary I/O.
 * Before running this, populate a database with the following commands
 * (provided in src/test/examples/testlibpq3.sql):
 */
CREATE TABLE test1 (i int4, t text, b bytea);

INSERT INTO test1 values (1, 'joe''s place', '\000\001\002\003\004');
INSERT INTO test1 values (2, 'ho there', '\004\003\002\001\000');

The expected output is:

tuple 0: got
  i = (4 bytes) 1
  t = (11 bytes) 'joe’s place'
  b = (5 bytes) \000\001\002\003\004

tuple 0: got
  i = (4 bytes) 2
  t = (8 bytes) 'ho there'
  b = (5 bytes) \004\003\002\001\000

    if (argc > 1)
        conninfo = argv[1];
else
    conninfo = "dbname = postgres";

/* Make a connection to the database */
conn = PQconnectdb(conninfo);

/* Check to see that the backend connection was successfully made */
if (PQstatus(conn) != CONNECTION_OK)
{
    fprintf(stderr, "Connection to database failed: %s",
        PQerrorMessage(conn));
    exit_nicely(conn);
}

/* The point of this program is to illustrate use of PQexecParams() with
 * out-of-line parameters, as well as binary transmission of data.
 * This first example transmits the parameters as text, but receives the
 * results in binary format. By using out-of-line parameters we can
 * avoid a lot of tedious mucking about with quoting and escaping, even
 * though the data is text. Notice how we don’t have to do anything
 * special with the quote mark in the parameter value.
 */

/* Here is our out-of-line parameter value */
paramValues[0] = "joe’s place";

res = PQexecParams(conn,
    "SELECT * FROM test1 WHERE t = $1",
    1,    /* one param */
    NULL,  /* let the backend deduce param type */
    paramValues,
    NULL,  /* don’t need param lengths since text */
    NULL,  /* default to all text params */
    1);  /* ask for binary results */

if (PQresultStatus(res) != PGRES_TUPLES_OK)
{
    fprintf(stderr, "SELECT failed: %s", PQerrorMessage(conn));
    PQclear(res);
    exit_nicely(conn);
}

show_binary_results(res);

PQclear(res);

/*
 * In this second example we transmit an integer parameter in binary
 * form, and again retrieve the results in binary form.
 * Although we tell PQexecParams we are letting the backend deduce
 * parameter type, we really force the decision by casting the parameter
 * symbol in the query text. This is a good safety measure when sending
 * binary parameters.
 */
/* Convert integer value "2" to network byte order */
binaryIntVal = htonl((uint32_t) 2);

/* Set up parameter arrays for PQexecParams */
paramValues[0] = (char *) &binaryIntVal;
paramLengths[0] = sizeof(binaryIntVal);
paramFormats[0] = 1; /* binary */

res = PQexecParams(conn,
"SELECT * FROM test1 WHERE i = $1::int4",
1, /* one param */
NULL, /* let the backend deduce param type */
paramValues,
paramLengths,
paramFormats,
1); /* ask for binary results */

if (PQresultStatus(res) != PGRES_TUPLES_OK)
{
    fprintf(stderr, "SELECT failed: %s", PQerrorMessage(conn));
PQclear(res);
    exit_nicely(conn);
}

show_binary_results(res);
PQclear(res);

/* close the connection to the database and cleanup */
PQfinish(conn);

return 0;

Chapter 31. Large Objects

PostgreSQL has a *large object* facility, which provides stream-style access to user data that is stored in a special large-object structure. Streaming access is useful when working with data values that are too large to manipulate conveniently as a whole.

This chapter describes the implementation and the programming and query language interfaces to PostgreSQL large object data. We use the libpq C library for the examples in this chapter, but most programming interfaces native to PostgreSQL support equivalent functionality. Other interfaces might use the large object interface internally to provide generic support for large values. This is not described here.

31.1. Introduction

All large objects are placed in a single system table called `pg_largeobject`. PostgreSQL also supports a storage system called “TOAST” that automatically stores values larger than a single database page into a secondary storage area per table. This makes the large object facility partially obsolete. One remaining advantage of the large object facility is that it allows values up to 2 GB in size, whereas TOASTed fields can be at most 1 GB. Also, large objects can be randomly modified using a read/write API that is more efficient than performing such operations using TOAST.

31.2. Implementation Features

The large object implementation breaks large objects up into “chunks” and stores the chunks in rows in the database. A B-tree index guarantees fast searches for the correct chunk number when doing random access reads and writes.

31.3. Client Interfaces

This section describes the facilities that PostgreSQL client interface libraries provide for accessing large objects. All large object manipulation using these functions must take place within an SQL transaction block. The PostgreSQL large object interface is modeled after the Unix file-system interface, with analogues of `open`, `read`, `write`, `lseek`, etc.

Client applications which use the large object interface in libpq should include the header file `libpq/libpq-fs.h` and link with the libpq library.

31.3.1. Creating a Large Object

The function

```c
Oid lo_creat(PGconn *conn, int mode);
```

creates a new large object. The return value is the OID that was assigned to the new large object, or `InvalidOid` (zero) on failure. `mode` is unused and ignored as of PostgreSQL 8.1; however, for backwards compatibility with earlier releases it is best to set it to `INV_READ`, `INV_WRITE`, or `INV_READ | INV_WRITE`. (These symbolic constants are defined in the header file `libpq/libpq-fs.h`.)
Chapter 31. Large Objects

31.3.2. Importing a Large Object

To import an operating system file as a large object, call

```c
Oid lo_import(PGconn *conn, const char *filename);
```

*filename* specifies the operating system name of the file to be imported as a large object. The return value is the OID that was assigned to the new large object, or InvalidOid (zero) on failure. Note that the file is read by the client interface library, not by the server; so it must exist in the client file system and be readable by the client application.

31.3.3. Exporting a Large Object

To export a large object into an operating system file, call

```c
int lo_export(PGconn *conn, Oid lobjId, const char *filename);
```

The *lobjId* argument specifies the OID of the large object to export and the *filename* argument specifies the operating system name of the file. Note that the file is written by the client interface library, not by the server. Returns 1 on success, -1 on failure.

31.3.4. Opening an Existing Large Object

To open an existing large object for reading or writing, call

```c
int lo_open(PGconn *conn, Oid lobjId, int mode);
```

The *lobjId* argument specifies the OID of the large object to open. The *mode* bits control whether the object is opened for reading (INV_READ), writing (INV_WRITE), or both. (These symbolic constants
A large object cannot be opened before it is created. `lo_open` returns a (non-negative) large object descriptor for later use in `lo_read`, `lo_write`, `lo_lseek`, `lo_tell`, and `lo_close`. The descriptor is only valid for the duration of the current transaction. On failure, -1 is returned.

The server currently does not distinguish between modes `INV_WRITE` and `INV_READ | INV_WRITE`: you are allowed to read from the descriptor in either case. However there is a significant difference between these modes and `INV_READ` alone: with `INV_READ` you cannot write on the descriptor, and the data read from it will reflect the contents of the large object at the time of the transaction snapshot that was active when `lo_open` was executed, regardless of later writes by this or other transactions. Reading from a descriptor opened with `INV_WRITE` returns data that reflects all writes of other committed transactions as well as writes of the current transaction. This is similar to the behavior of `SERIALIZABLE` versus `READ_COMMITTED` transaction modes for ordinary SQL `SELECT` commands.

An example:

```c
inv_fd = lo_open(conn, inv_oid, INV_READ|INV_WRITE);
```

### 31.3.5. Writing Data to a Large Object

The function

```c
int lo_write(PGconn *conn, int fd, const char *buf, size_t len);
```

writes `len` bytes from `buf` to large object descriptor `fd`. The `fd` argument must have been returned by a previous `lo_open`. The number of bytes actually written is returned. In the event of an error, the return value is negative.

### 31.3.6. Reading Data from a Large Object

The function

```c
int lo_read(PGconn *conn, int fd, char *buf, size_t len);
```

reads `len` bytes from large object descriptor `fd` into `buf`. The `fd` argument must have been returned by a previous `lo_open`. The number of bytes actually read is returned. In the event of an error, the return value is negative.

### 31.3.7. Seeking in a Large Object

To change the current read or write location associated with a large object descriptor, call

```c
int lo_lseek(PGconn *conn, int fd, int offset, int whence);
```

This function moves the current location pointer for the large object descriptor identified by `fd` to the new location specified by `offset`. The valid values for `whence` are `SEEK_SET` (seek from object start), `SEEK_CUR` (seek from current position), and `SEEK_END` (seek from object end). The return value is the new location pointer, or -1 on error.
31.3.8. Obtaining the Seek Position of a Large Object

To obtain the current read or write location of a large object descriptor, call

```c
int lo_tell(PGconn *conn, int fd);
```

If there is an error, the return value is negative.

31.3.9. Truncating a Large Object

To truncate a large object to a given length, call

```c
int lo_truncate(PGconn *conn, int fd, size_t len);
```

truncates the large object descriptor `fd` to length `len`. The `fd` argument must have been returned by a previous `lo_open`. If `len` is greater than the current large object length, the large object is extended with null bytes (`\0`).

The file offset is not changed.

On success `lo_truncate` returns zero. On error, the return value is negative.

`lo_truncate` is new as of PostgreSQL 8.3; if this function is run against an older server version, it will fail and return a negative value.

31.3.10. Closing a Large Object Descriptor

A large object descriptor can be closed by calling

```c
int lo_close(PGconn *conn, int fd);
```

where `fd` is a large object descriptor returned by `lo_open`. On success, `lo_close` returns zero. On error, the return value is negative.

Any large object descriptors that remain open at the end of a transaction will be closed automatically.

31.3.11. Removing a Large Object

To remove a large object from the database, call

```c
int lo_unlink(PGconn *conn, Oid lobjId);
```

The `lobjId` argument specifies the OID of the large object to remove. Returns 1 if successful, -1 on failure.

31.4. Server-Side Functions

There are server-side functions callable from SQL that correspond to each of the client-side functions described above; indeed, for the most part the client-side functions are simply interfaces to the equiva-
lent server-side functions. The ones that are actually useful to call via SQL commands are `lo_creat`, `lo_create`, `lo_unlink`, `lo_import`, and `lo_export`. Here are examples of their use:

```sql
CREATE TABLE image (  
    name text,  
    raster oid  
);  
SELECT lo_creat(-1);  -- returns OID of new, empty large object
SELECT lo_create(43213);  -- attempts to create large object with OID 43213
SELECT lo_unlink(173454);  -- deletes large object with OID 173454
INSERT INTO image (name, raster)  
    VALUES ('beautiful image', lo_import('/etc/motd'));
SELECT lo_export(image.raster, '/tmp/motd') FROM image  
    WHERE name = 'beautiful image';
```

The server-side `lo_import` and `lo_export` functions behave considerably differently from their client-side analogs. These two functions read and write files in the server’s file system, using the permissions of the database’s owning user. Therefore, their use is restricted to superusers. In contrast, the client-side import and export functions read and write files in the client’s file system, using the permissions of the client program. The client-side functions can be used by any PostgreSQL user.

### 31.5. Example Program

Example 31-1 is a sample program which shows how the large object interface in libpq can be used. Parts of the program are commented out but are left in the source for the reader’s benefit. This program can also be found in `src/test/examples/testlo.c` in the source distribution.

**Example 31-1. Large Objects with libpq Example Program**

```c
/*--------------------------------------------------------------
*    testlo.c--
*    test using large objects with libpq
*    Copyright (c) 1994, Regents of the University of California
*    --------------------------------------------------------------
*/
#include <stdio.h>
#include "libpq-fe.h"
#include "libpq/libpq-fs.h"
#define BUFSIZE 1024

/* importFile
* import file "in_filename" into database as large object "lobj0id"
* */
```
Chapter 31. Large Objects

```c
Oid
importFile(PGconn *conn, char *filename)
{
    Oid lobjId;
    int lobj_fd;
    char buf[BUFSIZE];
    int nbytes,
        tmp;
    int fd;

    /*
     * open the file to be read in
     */
    fd = open(filename, O_RDONLY, 0666);
    if (fd < 0)
    {
        /* error */
        fprintf(stderr, "cannot open unix file \%s\n", filename);
    }

    /*
     * create the large object
     */
    lobjId = lo_creat(conn, INV_READ | INV_WRITE);
    if (lobjId == 0)
        fprintf(stderr, "cannot create large object\n");

    lobj_fd = lo_open(conn, lobjId, INV_WRITE);

    /*
     * read in from the Unix file and write to the inversion file
     */
    while ((nbytes = read(fd, buf, BUFSIZE)) > 0)
    {
        tmp = lo_write(conn, lobj_fd, buf, nbytes);
        if (tmp < nbytes)
            fprintf(stderr, "error while reading large object\n");
    }

    (void) close(fd);
    (void) lo_close(conn, lobj_fd);

    return lobjId;
}

void
pickout(PGconn *conn, Oid lobjId, int start, int len)
{
    int lobj_fd;
    char *buf;
    int nbytes;
    int nread;

    lobj_fd = lo_open(conn, lobjId, INV_READ);
    if (lobj_fd < 0)
    {
        fprintf(stderr, "cannot open large object \%d\n",

lobjId);
}
lo_lseek(conn, lobj_fd, start, SEEK_SET);
buf = malloc(len + 1);

nread = 0;
while (len - nread > 0)
{
    nbytes = lo_read(conn, lobj_fd, buf, len - nread);
    buf[nbytes] = ' ';  
    fprintf(stderr, ">>>")
    fprintf(stderr, "%s", buf);
    nread += nbytes;
}
free(buf);
fprintf(stderr, "\n");
lo_close(conn, lobj_fd);
}

void overwrite(PGconn *conn, Oid lobjId, int start, int len)
{
    int lobj_fd;
    char *buf;
    int nbytes;
    int nwritten;
    int i;

    lobj_fd = lo_open(conn, lobjId, INV_WRITE);
    if (lobj_fd < 0)
    {
        fprintf(stderr, "cannot open large object %d\n", lobjId);
    }

    lo_lseek(conn, lobj_fd, start, SEEK_SET);
    buf = malloc(len + 1);

    for (i = 0; i < len; i++)
        buf[i] = 'X';
    buf[i] = ' ';
    nwritten = 0;
    while (len - nwritten > 0)
    {
        nbytes = lo_write(conn, lobj_fd, buf + nwritten, len - nwritten);
        nwritten += nbytes;
    }
    free(buf);
    fprintf(stderr, "\n");
    lo_close(conn, lobj_fd);
}

/ * exportFile
 * export large object "lobjOid" to file "out_filename"
 *
Chapter 31. Large Objects

```c
void
exportFile(PGconn *conn, Oid lobjId, char *filename)
{
    int lobj_fd;
    char buf[BUFSIZE];
    int nbytes,
        tmp;
    int fd;

    /*
    * open the large object
    */
    lobj_fd = lo_open(conn, lobjId, INV_READ);
    if (lobj_fd < 0)
    {
        fprintf(stderr, "cannot open large object %d\n",
                lobjId);
    }

    /*
    * open the file to be written to
    */
    fd = open(filename, O_CREAT | O_WRONLY, 0666);
    if (fd < 0)
    {
        /* error */
        fprintf(stderr, "cannot open unix file %s\n",
                filename);
    }

    /*
    * read in from the inversion file and write to the Unix file
    */
    while ((nbytes = lo_read(conn, lobj_fd, buf, BUFSIZE)) > 0)
    {
        tmp = write(fd, buf, nbytes);
        if (tmp < nbytes)
        {
            fprintf(stderr, "error while writing %s\n",
                    filename);
        }
    }

    (void) lo_close(conn, lobj_fd);
    (void) close(fd);

    return;
}

void
exit_nicely(PGconn *conn)
{
    PQfinish(conn);
    exit(1);
}

int
```
main(int argc, char **argv) {
    char *in_filename,
        *out_filename;
    char *database;
    Oid  lobjOid;
    PGconn *conn;
    PGresult *res;

    if (argc != 4) {
        fprintf(stderr, "Usage: %s database_name in_filename out_filename\n", argv[0]);
        exit(1);
    }

    database = argv[1];
    in_filename = argv[2];
    out_filename = argv[3];

    /* set up the connection */
    conn = PQsetdb(NULL, NULL, NULL, NULL, database);

    /* check to see that the backend connection was successfully made */
    if (PQstatus(conn) == CONNECTION_BAD) {
        fprintf(stderr, "Connection to database '%s' failed.\n", database);
        fprintf(stderr, "%s", PQerrorMessage(conn));
        exit_nicely(conn);
    }

    res = PQexec(conn, "begin");

    overwrite(conn, lobjOid, 1000, 1000);

    printf("exporting large object to file %s\n", out_filename);
    lo_export(conn, lobjOid, out_filename);

    res = PQexec(conn, "end");
    PQclear(res);
    PQfinish(conn);
    exit(0);
}
Chapter 32. ECPG - Embedded SQL in C

This chapter describes the embedded SQL package for PostgreSQL. It was written by Linus Tolke (<linus@epact.se>) and Michael Meskes (<meskes@postgresql.org>). Originally it was written to work with C. It also works with C++, but it does not recognize all C++ constructs yet.

This documentation is quite incomplete. But since this interface is standardized, additional information can be found in many resources about SQL.

32.1. The Concept

An embedded SQL program consists of code written in an ordinary programming language, in this case C, mixed with SQL commands in specially marked sections. To build the program, the source code is first passed through the embedded SQL preprocessor, which converts it to an ordinary C program, and afterwards it can be processed by a C compiler.

Embedded SQL has advantages over other methods for handling SQL commands from C code. First, it takes care of the tedious passing of information to and from variables in your C program. Second, the SQL code in the program is checked at build time for syntactical correctness. Third, embedded SQL in C is specified in the SQL standard and supported by many other SQL database systems. The PostgreSQL implementation is designed to match this standard as much as possible, and it is usually possible to port embedded SQL programs written for other SQL databases to PostgreSQL with relative ease.

As already stated, programs written for the embedded SQL interface are normal C programs with special code inserted to perform database-related actions. This special code always has the form:

EXEC SQL ...;

These statements syntactically take the place of a C statement. Depending on the particular statement, they can appear at the global level or within a function. Embedded SQL statements follow the case-sensitivity rules of normal SQL code, and not those of C.

The following sections explain all the embedded SQL statements.

32.2. Connecting to the Database Server

One connects to a database using the following statement:

EXEC SQL CONNECT TO target [AS connection-name] [USER user-name];

The target can be specified in the following ways:

- dbname[@hostname][:port]
- tcp:postgresql://hostname[:port]/dbname[?options]
- unix:postgresql://hostname[:port]/dbname[?options]
- an SQL string literal containing one of the above forms
- a reference to a character variable containing one of the above forms (see examples)
- DEFAULT
If you specify the connection target literally (that is, not through a variable reference) and you don’t quote the value, then the case-insensitivity rules of normal SQL are applied. In that case you can also double-quote the individual parameters separately as needed. In practice, it is probably less error-prone to use a (single-quoted) string literal or a variable reference. The connection target DEFAULT initiates a connection to the default database under the default user name. No separate user name or connection name can be specified in that case.

There are also different ways to specify the user name:

- `username`
- `username/password`
- `username IDENTIFIED BY password`
- `username USING password`

As above, the parameters `username` and `password` can be an SQL identifier, an SQL string literal, or a reference to a character variable.

The connection-name is used to handle multiple connections in one program. It can be omitted if a program uses only one connection. The most recently opened connection becomes the current connection, which is used by default when an SQL statement is to be executed (see later in this chapter).

Here are some examples of `CONNECT` statements:

```sql
EXEC SQL CONNECT TO mydb@sql.mydomain.com;
EXEC SQL CONNECT TO unix:postgresql://sql.mydomain.com/mydb AS myconnection USER john;
EXEC SQL BEGIN DECLARE SECTION;
const char *target = "mydb@sql.mydomain.com";
const char *user = "john";
EXEC SQL END DECLARE SECTION;
EXEC SQL CONNECT TO :target USER :user;
```

The last form makes use of the variant referred to above as character variable reference. You will see in later sections how C variables can be used in SQL statements when you prefix them with a colon. Be advised that the format of the connection target is not specified in the SQL standard. So if you want to develop portable applications, you might want to use something based on the last example above to encapsulate the connection target string somewhere.

### 32.3. Closing a Connection

To close a connection, use the following statement:

```sql
EXEC SQL DISCONNECT [connection];
```

The `connection` can be specified in the following ways:

- `connection-name`
- `DEFAULT`
If no connection name is specified, the current connection is closed.
It is good style that an application always explicitly disconnect from every connection it opened.

32.4. Running SQL Commands

Any SQL command can be run from within an embedded SQL application. Below are some examples of how to do that.

Creating a table:

EXEC SQL CREATE TABLE foo (number integer, ascii char(16));
EXEC SQL CREATE UNIQUE INDEX num1 ON foo(number);
EXEC SQL COMMIT;

Inserting rows:

EXEC SQL INSERT INTO foo (number, ascii) VALUES (9999, 'doodad');
EXEC SQL COMMIT;

Deleting rows:

EXEC SQL DELETE FROM foo WHERE number = 9999;
EXEC SQL COMMIT;

Single-row select:

EXEC SQL SELECT foo INTO :FooBar FROM table1 WHERE ascii = 'doodad';

Select using cursors:

EXEC SQL DECLARE foo_bar CURSOR FOR
SELECT number, ascii FROM foo
ORDER BY ascii;
EXEC SQL OPEN foo_bar;
EXEC SQL FETCH foo_bar INTO :FooBar, DooDad;
... EXEC SQL CLOSE foo_bar;
EXEC SQL COMMIT;

Updates:

EXEC SQL UPDATE foo
SET ascii = 'foobar'
WHERE number = 9999;
EXEC SQL COMMIT;
Chapter 32. ECPG - Embedded SQL in C

The tokens of the form :something are host variables, that is, they refer to variables in the C program. They are explained in Section 32.6.

In the default mode, statements are committed only when EXEC SQL COMMIT is issued. The embedded SQL interface also supports autocommit of transactions (similar to libpq behavior) via the -t command-line option to ecpg (see below) or via the EXEC SQL SET AUTOCOMMIT TO ON statement. In autocommit mode, each command is automatically committed unless it is inside an explicit transaction block. This mode can be explicitly turned off using EXEC SQL SET AUTOCOMMIT TO OFF.

32.5. Choosing a Connection

The SQL statements shown in the previous section are executed on the current connection, that is, the most recently opened one. If an application needs to manage multiple connections, then there are two ways to handle this.

The first option is to explicitly choose a connection for each SQL statement, for example:

EXEC SQL AT connection-name SELECT ...;

This option is particularly suitable if the application needs to use several connections in mixed order. If your application uses multiple threads of execution, they cannot share a connection concurrently. You must either explicitly control access to the connection (using mutexes) or use a connection for each thread. If each thread uses its own connection, you will need to use the AT clause to specify which connection the thread will use.

The second option is to execute a statement to switch the current connection. That statement is:

EXEC SQL SET CONNECTION connection-name;

This option is particularly convenient if many statements are to be executed on the same connection. It is not thread-aware.

32.6. Using Host Variables

In Section 32.4 you saw how you can execute SQL statements from an embedded SQL program. Some of those statements only used fixed values and did not provide a way to insert user-supplied values into statements or have the program process the values returned by the query. Those kinds of statements are not really useful in real applications. This section explains in detail how you can pass data between your C program and the embedded SQL statements using a simple mechanism called host variables. In an embedded SQL program we consider the SQL statements to be guests in the C program code which is the host language. Therefore the variables of the C program are called host variables.

32.6.1. Overview

Passing data between the C program and the SQL statements is particularly simple in embedded SQL. Instead of having the program paste the data into the statement, which entails various complications,
such as properly quoting the value, you can simply write the name of a C variable into the SQL statement, prefixed by a colon. For example:

```sql
EXEC SQL INSERT INTO sometable VALUES (:v1, 'foo', :v2);
```

This statements refers to two C variables named `v1` and `v2` and also uses a regular SQL string literal, to illustrate that you are not restricted to use one kind of data or the other.

This style of inserting C variables in SQL statements works anywhere a value expression is expected in an SQL statement.

### 32.6.2. Declare Sections

To pass data from the program to the database, for example as parameters in a query, or to pass data from the database back to the program, the C variables that are intended to contain this data need to be declared in specially marked sections, so the embedded SQL preprocessor is made aware of them.

This section starts with:

```sql
EXEC SQL BEGIN DECLARE SECTION;
```

and ends with:

```sql
EXEC SQL END DECLARE SECTION;
```

Between those lines, there must be normal C variable declarations, such as:

```c
int x = 4;
char foo[16], bar[16];
```

As you can see, you can optionally assign an initial value to the variable. The variable’s scope is determined by the location of its declaring section within the program. You can also declare variables with the following syntax which implicitly creates a declare section:

```sql
EXEC SQL int i = 4;
```

You can have as many declare sections in a program as you like.

The declarations are also echoed to the output file as normal C variables, so there’s no need to declare them again. Variables that are not intended to be used in SQL commands can be declared normally outside these special sections.

The definition of a structure or union also must be listed inside a DECLARE section. Otherwise the preprocessor cannot handle these types since it does not know the definition.

### 32.6.3. Different types of host variables

As a host variable you can also use arrays, typedefs, structs and pointers. Moreover there are special types of host variables that exist only in ECPG.

A few examples on host variables:
Arrays

One of the most common uses of an array declaration is probably the allocation of a char array as in:

EXEC SQL BEGIN DECLARE SECTION;
    char str[50];
EXEC SQL END DECLARE SECTION;

Note that you have to take care of the length for yourself. If you use this host variable as the target variable of a query which returns a string with more than 49 characters, a buffer overflow occurs.

Typedefs

Use the typedef keyword to map new types to already existing types.

EXEC SQL BEGIN DECLARE SECTION;
    typedef char mychartype[40];
    typedef long serial_t;
EXEC SQL END DECLARE SECTION;

Note that you could also use:

EXEC SQL TYPE serial_t IS long;

This declaration does not need to be part of a declare section.

Pointers

You can declare pointers to the most common types. Note however that you cannot use pointers as target variables of queries without auto-allocation. See Section 32.10 for more information on auto-allocation.

EXEC SQL BEGIN DECLARE SECTION;
    int  *intp;
    char **charp;
EXEC SQL END DECLARE SECTION;

Special types of variables

ECPG contains some special types that help you to interact easily with data from the SQL server. For example it has implemented support for the varchar, numeric, date, timestamp, and interval types. Section 32.8 contains basic functions to deal with those types, such that you do not need to send a query to the SQL server just for adding an interval to a timestamp for example.

The special type VARCHAR is converted into a named struct for every variable. A declaration like:

VARCHAR var[180];

is converted into:

struct varchar_var { int len; char arr[180]; } var;

This structure is suitable for interfacing with SQL datums of type varchar.

32.6.4. SELECT INTO and FETCH INTO

Now you should be able to pass data generated by your program into an SQL command. But how do you retrieve the results of a query? For that purpose, embedded SQL provides special variants of the usual commands SELECT and FETCH. These commands have a special INTO clause that specifies which host variables the retrieved values are to be stored in.
Chapter 32. ECPG - Embedded SQL in C

Here is an example:

```
/*
 * assume this table:
 * CREATE TABLE test1 (a int, b varchar(50));
 */
EXEC SQL BEGIN DECLARE SECTION;
    int v1;
    VARCHAR v2;
EXEC SQL END DECLARE SECTION;

EXEC SQL SELECT a, b INTO :v1, :v2 FROM test;
```

So the INTO clause appears between the select list and the FROM clause. The number of elements in the select list and the list after INTO (also called the target list) must be equal.

Here is an example using the command FETCH:

```
EXEC SQL BEGIN DECLARE SECTION;
    int v1;
    VARCHAR v2;
EXEC SQL END DECLARE SECTION;

EXEC SQL DECLARE foo CURSOR FOR SELECT a, b FROM test;

... do {
    ... 
    EXEC SQL FETCH NEXT FROM foo INTO :v1, :v2;
    ...
} while (...);
```

Here the INTO clause appears after all the normal clauses.

Both of these methods only allow retrieving one row at a time. If you need to process result sets that potentially contain more than one row, you need to use a cursor, as shown in the second example.

### 32.6.5. Indicators

The examples above do not handle null values. In fact, the retrieval examples will raise an error if they fetch a null value from the database. To be able to pass null values to the database or retrieve null values from the database, you need to append a second host variable specification to each host variable that contains data. This second host variable is called the indicator and contains a flag that tells whether the datum is null, in which case the value of the real host variable is ignored. Here is an example that handles the retrieval of null values correctly:

```
EXEC SQL BEGIN DECLARE SECTION;
    VARCHAR val;
    int val_ind;
EXEC SQL END DECLARE SECTION;
```
EXEC SQL SELECT b INTO :val :val_ind FROM test1;

The indicator variable \( \text{val\_ind} \) will be zero if the value was not null, and it will be negative if the value was null.

The indicator has another function: if the indicator value is positive, it means that the value is not null, but it was truncated when it was stored in the host variable.

### 32.7. Dynamic SQL

In many cases, the particular SQL statements that an application has to execute are known at the time the application is written. In some cases, however, the SQL statements are composed at run time or provided by an external source. In these cases you cannot embed the SQL statements directly into the C source code, but there is a facility that allows you to call arbitrary SQL statements that you provide in a string variable.

The simplest way to execute an arbitrary SQL statement is to use the command `EXECUTE IMMEDIATE`. For example:

```c
EXEC SQL BEGIN DECLARE SECTION;
const char *stmt = "CREATE TABLE test1 (...);";
EXEC SQL END DECLARE SECTION;
EXEC SQL EXECUTE IMMEDIATE :stmt;
```

You cannot execute statements that retrieve data (e.g., `SELECT`) this way.

A more powerful way to execute arbitrary SQL statements is to prepare them once and execute the prepared statement as often as you like. It is also possible to prepare a generalized version of a statement and then execute specific versions of it by substituting parameters. When preparing the statement, write question marks where you want to substitute parameters later. For example:

```c
EXEC SQL BEGIN DECLARE SECTION;
const char *stmt = "INSERT INTO test1 VALUES(?, ?);";
EXEC SQL END DECLARE SECTION;
EXEC SQL PREPARE mystmt FROM :stmt;
...
EXEC SQL EXECUTE mystmt USING 42, 'foobar';
```

If the statement you are executing returns values, then add an `INTO` clause:

```c
EXEC SQL BEGIN DECLARE SECTION;
const char *stmt = "SELECT a, b, c FROM test1 WHERE a > ?";
int v1, v2;
VARCHAR v3;
EXEC SQL END DECLARE SECTION;
EXEC SQL PREPARE mystmt FROM :stmt;
...
EXEC SQL EXECUTE mystmt INTO v1, v2, v3 USING 37;
```
Chapter 32. ECPG - Embedded SQL in C

An **EXECUTE** command can have an **INTO** clause, a **USING** clause, both, or neither.

When you don’t need the prepared statement anymore, you should deallocate it:

EXEC SQL DEALLOCATE PREPARE name;

### 32.8. pgtypes library

The pgtypes library maps PostgreSQL database types to C equivalents that can be used in C programs. It also offers functions to do basic calculations with those types within C, i.e. without the help of the PostgreSQL server. See the following example:

```sql
EXEC SQL BEGIN DECLARE SECTION;
    date date1;
    timestamp ts1, tsout;
    interval iv1;
    char *out;
EXEC SQL END DECLARE SECTION;

PGTYPESdate_today(&date1);
EXEC SQL SELECT started, duration INTO :ts1, :iv1 FROM datetbl WHERE d=:date1;
PGTYPEStimestamp_add_interval(&ts1, &iv1, &tsout);
out = PGTYPEStimestamp_to_asc(&tsout);
printf("Started + duration: %s\n", out);
free(out);
```

### 32.8.1. The numeric type

The numeric type offers to do calculations with arbitrary precision. See Section 8.1 for the equivalent type in the PostgreSQL server. Because of the arbitrary precision this variable needs to be able to expand and shrink dynamically. That’s why you can only create variables on the heap by means of the **PGTYPESnumeric_new** and **PGTYPESnumeric_free** functions. The decimal type, which is similar but limited in the precision, can be created on the stack as well as on the heap.

The following functions can be used to work with the numeric type:

**PGTYPESnumeric_new**

Request a pointer to a newly allocated numeric variable.

```c
numeric *PGTYPESnumeric_new(void);
```

**PGTYPESnumeric_free**

Free a numeric type, release all of its memory.

```c
void PGTYPESnumeric_free(numeric *var);
```

**PGTYPESnumeric_from_asc**

Parse a numeric type from its string notation.

```c
numeric *PGTYPESnumeric_from_asc(char *str, char **endptr);
```
Valid formats are for example: \(-2.794, +3.44, 592.49E07\) or \(-32.84e-4\). If the value could be parsed successfully, a valid pointer is returned, else the NULL pointer. At the moment ecpg always parses the complete string and so it currently does not support to store the address of the first invalid character in \(*\text{endptr}\). You can safely set \text{endptr}\ to NULL.

\textbf{PGTYPESnumeric_to_asc}

Returns a pointer to a string allocated by \text{malloc} that contains the string representation of the numeric type \text{num}.

\begin{verbatim}
char *PGTYPESnumeric_to_asc(numeric *num, int dscale);
The numeric value will be printed with \text{dscale} decimal digits, with rounding applied if necessary.
\end{verbatim}

\textbf{PGTYPESnumeric_add}

Add two numeric variables into a third one.

\begin{verbatim}
int PGTYPESnumeric_add(numeric *var1, numeric *var2, numeric *result);
The function adds the variables \text{var1} and \text{var2} into the result variable \text{result}. The function returns 0 on success and -1 in case of error.
\end{verbatim}

\textbf{PGTYPESnumeric_sub}

Subtract two numeric variables and return the result in a third one.

\begin{verbatim}
int PGTYPESnumeric_sub(numeric *var1, numeric *var2, numeric *result);
The function subtracts the variable \text{var2} from the variable \text{var1}. The result of the operation is stored in the variable \text{result}. The function returns 0 on success and -1 in case of error.
\end{verbatim}

\textbf{PGTYPESnumeric_mul}

Multiply two numeric variables and return the result in a third one.

\begin{verbatim}
int PGTYPESnumeric_mul(numeric *var1, numeric *var2, numeric *result);
The function multiplies the variables \text{var1} and \text{var2}. The result of the operation is stored in the variable \text{result}. The function returns 0 on success and -1 in case of error.
\end{verbatim}

\textbf{PGTYPESnumeric_div}

Divide two numeric variables and return the result in a third one.

\begin{verbatim}
int PGTYPESnumeric_div(numeric *var1, numeric *var2, numeric *result);
The function divides the variables \text{var1} by \text{var2}. The result of the operation is stored in the variable \text{result}. The function returns 0 on success and -1 in case of error.
\end{verbatim}

\textbf{PGTYPESnumeric_cmp}

Compare two numeric variables.

\begin{verbatim}
int PGTYPESnumeric_cmp(numeric *var1, numeric *var2)
This function compares two numeric variables. In case of error, \text{INT\_MAX} is returned. On success, the function returns one of three possible results:
\begin{itemize}
  \item 1, if \text{var1} is bigger than \text{var2}
  \item -1, if \text{var1} is smaller than \text{var2}
  \item 0, if \text{var1} and \text{var2} are equal
\end{itemize}
\end{verbatim}

\textbf{PGTYPESnumeric_from_int}

Convert an int variable to a numeric variable.

\begin{verbatim}
int PGTYPESnumeric_from_int(signed int int_val, numeric *var);
\end{verbatim}
Chapter 32. ECPG - Embedded SQL in C

This function accepts a variable of type signed int and stores it in the numeric variable var. Upon success, 0 is returned and -1 in case of a failure.

PGTYPESnumeric_from_long

Convert a long int variable to a numeric variable.

```
int PGTYPESnumeric_from_long(signed long int long_val, numeric *var);
```

This function accepts a variable of type signed long int and stores it in the numeric variable var. Upon success, 0 is returned and -1 in case of a failure.

PGTYPESnumeric_copy

Copy over one numeric variable into another one.

```
int PGTYPESnumeric_copy(numeric *src, numeric *dst);
```

This function copies over the value of the variable that src points to into the variable that dst points to. It returns 0 on success and -1 if an error occurs.

PGTYPESnumeric_from_double

Convert a variable of type double to a numeric.

```
int PGTYPESnumeric_from_double(double d, numeric *dst);
```

This function accepts a variable of type double and stores the result in the variable that dst points to. It returns 0 on success and -1 if an error occurs.

PGTYPESnumeric_to_double

Convert a variable of type numeric to double.

```
int PGTYPESnumeric_to_double(numeric *nv, double *dp)
```

The function converts the numeric value from the variable that nv points to into the double variable that dp points to. It returns 0 on success and -1 if an error occurs, including overflow. On overflow, the global variable errno will be set to PGTYPES_NUM_OVERFLOW additionally.

PGTYPESnumeric_to_int

Convert a variable of type numeric to int.

```
int PGTYPESnumeric_to_int(numeric *nv, int *ip);
```

The function converts the numeric value from the variable that nv points to into the integer variable that ip points to. It returns 0 on success and -1 if an error occurs, including overflow. On overflow, the global variable errno will be set to PGTYPES_NUM_OVERFLOW additionally.

PGTYPESnumeric_to_long

Convert a variable of type numeric to long.

```
int PGTYPESnumeric_to_long(numeric *nv, long *lp);
```

The function converts the numeric value from the variable that nv points to into the long integer variable that lp points to. It returns 0 on success and -1 if an error occurs, including overflow. On overflow, the global variable errno will be set to PGTYPES_NUM_OVERFLOW additionally.

PGTYPESnumeric_to_decimal

Convert a variable of type numeric to decimal.

```
int PGTYPESnumeric_to_decimal(numeric *src, decimal *dst);
```

The function converts the numeric value from the variable that src points to into the decimal variable that dst points to. It returns 0 on success and -1 if an error occurs, including overflow. On overflow, the global variable errno will be set to PGTYPES_NUM_OVERFLOW additionally.
PGTYPESnumeric_from_decimal

Convert a variable of type decimal to numeric.

int PGTYPESnumeric_from_decimal(decimal *src, numeric *dst);

The function converts the decimal value from the variable that src points to into the numeric variable that dst points to. It returns 0 on success and -1 if an error occurs. Since the decimal type is implemented as a limited version of the numeric type, overflow cannot occur with this conversion.

32.8.2. The date type

The date type in C enables your programs to deal with data of the SQL type date. See Section 8.5 for the equivalent type in the PostgreSQL server.

The following functions can be used to work with the date type:

PGTYPESdate_from_timestamp

Extract the date part from a timestamp.

date PGTYPESdate_from_timestamp(timestamp dt);

The function receives a timestamp as its only argument and returns the extracted date part from this timestamp.

PGTYPESdate_from_asc

Parse a date from its textual representation.

date PGTYPESdate_from_asc(char *str, char **endptr);

The function receives a C char* string str and a pointer to a C char* string endptr. At the moment ecpg always parses the complete string and so it currently does not support to store the address of the first invalid character in *endptr. You can safely set endptr to NULL.

Note that the function always assumes MDY-formatted dates and there is currently no variable to change that within ecpg.

The following input formats are allowed:

Table 32-1. Valid input formats for PGTYPESdate_from_asc

<table>
<thead>
<tr>
<th>Input</th>
<th>Result</th>

<td>Julian day</td>
</tr>
<tr>
<td>January 8, 99 BC</td>
<td>year 99 before the Common Era</td>
</tr>
</tbody>
</table>

PGTYPESdate_to_asc

Return the textual representation of a date variable.

```c
char *PGTYPESdate_to_asc(date dDate);
```

The function receives the date `dDate` as its only parameter. It will output the date in the form `1999-01-18`, i.e. in the `YYYY-MM-DD` format.

PGTYPESdate_julmdy

Extract the values for the day, the month and the year from a variable of type date.

```c
void PGTYPESdate_julmdy(date d, int *mdy);
```

The function receives the date `d` and a pointer to an array of 3 integer values `mdy`. The variable name indicates the sequential order: `mdy[0]` will be set to contain the number of the month, `mdy[1]` will be set to the value of the day and `mdy[2]` will contain the year.

PGTYPESdate_mdyjul

Create a date value from an array of 3 integers that specify the day, the month and the year of the date.

```c
void PGTYPESdate_mdyjul(int *mdy, date *jdate);
```

The function receives the array of the 3 integers (`mdy`) as its first argument and as its second argument a pointer to a variable of type date that should hold the result of the operation.

PGTYPESdate_dayofweek

Return a number representing the day of the week for a date value.

```c
int PGTYPESdate_dayofweek(date d);
```

The function receives the date variable `d` as its only argument and returns an integer that indicates the day of the week for this date.

- 0 - Sunday
- 1 - Monday
- 2 - Tuesday
- 3 - Wednesday
- 4 - Thursday
- 5 - Friday
- 6 - Saturday

PGTYPESdate_today

Get the current date.

```c
void PGTYPESdate_today(date *d);
```

The function receives a pointer to a date variable (`d`) that it sets to the current date.
PGTYPESdate_fmt_asc

Convert a variable of type date to its textual representation using a format mask.

```c
int PGTYPESdate_fmt_asc(date dDate, char *fmtstring, char *outbuf);
```

The function receives the date to convert (dDate), the format mask (fmtstring) and the string that will hold the textual representation of the date (outbuf).

On success, 0 is returned and a negative value if an error occurred.

The following literals are the field specifiers you can use:

- `dd` - The number of the day of the month.
- `mm` - The number of the month of the year.
- `yy` - The number of the year as a two digit number.
- `yyyy` - The number of the year as a four digit number.
- `ddd` - The name of the day (abbreviated).
- `mmm` - The name of the month (abbreviated).

All other characters are copied 1:1 to the output string.

The following table indicates a few possible formats. This will give you an idea of how to use this function. All output lines are based on the same date: November, 23rd, 1959.

<table>
<thead>
<tr>
<th>fmt</th>
<th>result</th>
</tr>
</thead>
<tbody>
<tr>
<td>mnddyy</td>
<td>112359</td>
</tr>
<tr>
<td>ddmmyy</td>
<td>231159</td>
</tr>
<tr>

<td>591123</td>
</tr>
<tr>
<td>yy/mm/dd</td>
<td>59/11/23</td>
</tr>
<tr>
<td>yy mm dd</td>
<td>59 11 23</td>
</tr>
<tr>
<td>yyyy dd mm</td>
<td>1959 23 11</td>
</tr>
<tr>
<td>.mm.yyyy.dd.</td>
<td>.11.1959.23.</td>
</tr>
<tr>
<td>mmm. dd, yyyy</td>
<td>Nov. 23, 1959</td>
</tr>
<tr>
<td>mmm dd yyyy</td>
<td>Nov 23 1959</td>
</tr>
<tr>
<td>yyyy dd mm</td>
<td>1959 23 11</td>
</tr>
<tr>
<td>(ddd) mmm. dd, yyyy</td>
<td>Mon, Nov. 23, 1959</td>
</tr>
</tbody>
</table>

PGTYPESdate_defmt_asc

Use a format mask to convert a C char* string to a value of type date.

```c
int PGTYPESdate_defmt_asc(date *d, char *fmt, char *str);
```

The function receives a pointer to the date value that should hold the result of the operation (d), the format mask to use for parsing the date (fmt) and the C char* string containing the textual representation of the date (str). The textual representation is expected to match the format mask. However you do not need to have a 1:1 mapping of the string to the format mask. The function only analyzes the sequential order and looks for the literals `yy` or `yyyy` that indicate the position of the year, `mm` to indicate the position of the month and `dd` to indicate the position of the day.
The following table indicates a few possible formats. This will give you an idea of how to use this function.

</tbody>
</table>

32.8.3. The timestamp type

The timestamp type in C enables your programs to deal with data of the SQL type timestamp. See Section 8.5 for the equivalent type in the PostgreSQL server.

The following functions can be used to work with the timestamp type:

\texttt{PGTYPEStimestamp\_from\_asc}

Parse a timestamp from its textual representation into a timestamp variable.

\begin{verbatim}
timestamp PGTYPEStimestamp_from_asc(char *str, char **endptr);
\end{verbatim}

The function receives the string to parse (\texttt{str}) and a pointer to a C char* (\texttt{endptr}). At the moment ecpg always parses the complete string and so it currently does not support to store the address of the first invalid character in \texttt{*endptr}. You can safely set \texttt{endptr} to NULL.

The function returns the parsed timestamp on success. On error, \texttt{PGTYPESInvalidTimestamp} is returned and \texttt{errno} is set to \texttt{PGTYPES\_TS\_BAD\_TIMESTAMP}. See \texttt{PGTYPESInvalidTimestamp} for important notes on this value.

In general, the input string can contain any combination of an allowed date specification, a whitespace character and an allowed time specification. Note that timezones are not supported by ecpg. It can parse them but does not apply any calculation as the PostgreSQL server does for example. Timezone specifiers are silently discarded.
The following table contains a few examples for input strings:

<table>
<thead>
<tr>
<th>Input</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>1999-01-08 04:05:06</td>
<td>1999-01-08 04:05:06</td>
</tr>
<tr>
<td>January 8 04:05:06 1999 PST</td>
<td>1999-01-08 04:05:06</td>
</tr>
<tr>
<td>1999-Jan-08 04:05:06.789-8</td>
<td>1999-01-08 04:05:06.789 (time zone specifier ignored)</td>
</tr>
<tr>
<td>J2451187 04:05-08:00</td>
<td>1999-01-08 04:05:00 (time zone specifier ignored)</td>
</tr>
</tbody>
</table>

**PGTYPEStimestamp_to_asc**

Converts a date to a C char* string.

```c
char *PGTYPEStimestamp_to_asc(timestamp tstamp);
```

The function receives the timestamp `tstamp` as its only argument and returns an allocated string that contains the textual representation of the timestamp.

**PGTYPEStimestamp_current**

Retrieve the current timestamp.

```c
void PGTYPEStimestamp_current(timestamp *ts);
```

The function retrieves the current timestamp and saves it into the timestamp variable that `ts` points to.

**PGTYPEStimestamp_fmt_asc**

Convert a timestamp variable to a C char* using a format mask.

```c
int PGTYPEStimestamp_fmt_asc(timestamp *ts, char *output, int str_len, char *fmtstr);
```

The function receives a pointer to the timestamp to convert as its first argument (`ts`), a pointer to the output buffer (`output`), the maximal length that has been allocated for the output buffer (`str_len`) and the format mask to use for the conversion (`fmtstr`).

Upon success, the function returns 0 and a negative value if an error occurred.

You can use the following format specifiers for the format mask. The format specifiers are the same ones that are used in the `strftime` function in libc. Any non-format specifier will be copied into the output buffer.

- `%A` - is replaced by national representation of the full weekday name.
- `%a` - is replaced by national representation of the abbreviated weekday name.
- `%B` - is replaced by national representation of the full month name.
- `%b` - is replaced by national representation of the abbreviated month name.
- `%C` - is replaced by (year / 100) as decimal number; single digits are preceded by a zero.
- `%c` - is replaced by national representation of time and date.
- `%d` - is equivalent to `%m/%d/%y.`
- `%e` - is replaced by the day of the month as a decimal number (01-31).
- `%F` - POSIX locale extensions. The sequences `%Ec %EC %Ex %EX %Ey %EY %Od %Oe %OH %OI %OM %OS %Ou %OU %OV %OW %Oy` are supposed to provide alternative representations.
Additionally %OB implemented to represent alternative months names (used standalone, without day mentioned).

- %e - is replaced by the day of month as a decimal number (1-31); single digits are preceded by a blank.
- %F - is equivalent to %Y-%m-%d.
- %G - is replaced by a year as a decimal number with century. This year is the one that contains the greater part of the week (Monday as the first day of the week).
- %g - is replaced by the same year as in %G, but as a decimal number without century (00-99).
- %H - is replaced by the hour (24-hour clock) as a decimal number (00-23).
- %h - the same as %b.
- %I - is replaced by the hour (12-hour clock) as a decimal number (01-12).
- %j - is replaced by the day of the year as a decimal number (001-366).
- %k - is replaced by the hour (24-hour clock) as a decimal number (0-23); single digits are preceded by a blank.
- %l - is replaced by the hour (12-hour clock) as a decimal number (1-12); single digits are preceded by a blank.
- %M - is replaced by the minute as a decimal number (00-59).
- %m - is replaced by the month as a decimal number (01-12).
- %n - is replaced by a newline.
- %O* - the same as %E*.
- %p - is replaced by national representation of either "ante meridiem" or "post meridiem" as appropriate.
- %R - is equivalent to %H:%M.
- %T - is equivalent to %H:%M:%S
- %t - is replaced by a tab.
- %u - is replaced by the week number of the year (Sunday as the first day of the week) as a decimal number (00-53).
- %w - is replaced by the weekday (Monday as the first day of the week) as a decimal number (1-7).
- %V - is replaced by the week number of the year (Monday as the first day of the week) as a decimal number (01-53). If the week containing January 1 has four or more days in the new year, then it is week 1; otherwise it is the last week of the previous year, and the next week is week 1.
- %v - is equivalent to %e-%b-%Y.
- %W - is replaced by the week number of the year (Sunday as the first day of the week) as a decimal number (00-53).
- %w - is replaced by the weekday (Sunday as the first day of the week) as a decimal number (0-6).
Chapter 32. ECPG - Embedded SQL in C

• %X - is replaced by national representation of the time.
• %x - is replaced by national representation of the date.
• %Y - is replaced by the year with century as a decimal number.
• %y - is replaced by the year without century as a decimal number (00-99).
• %z - is replaced by the time zone name.
• %Z - is replaced by the time zone offset from UTC; a leading plus sign stands for east of UTC, a minus sign for west of UTC, hours and minutes follow with two digits each and no delimiter between them (common form for RFC 822 date headers).
• +% - is replaced by national representation of the date and time.
• %-- - GNU libc extension. Do not do any padding when performing numerical outputs.
• %*- - GNU libc extension. Explicitly specify space for padding.
• %0*- - GNU libc extension. Explicitly specify zero for padding.
• %% - is replaced by %.

PGTYPEStimestamp_sub
Subtract one timestamp from another one and save the result in a variable of type interval.
int PGTYPEStimestamp_sub(timestamp *ts1, timestamp *ts2, interval *iv);
The function will subtract the timestamp variable that ts2 points to from the timestamp variable that ts1 points to and will store the result in the interval variable that iv points to.
Upon success, the function returns 0 and a negative value if an error occurred.

PGTYPEStimestamp_defmt_asc
Parse a timestamp value from its textual representation using a formatting mask.
int PGTYPEStimestamp_defmt_asc(char *str, char *fmt, timestamp *d);
The function receives the textual representation of a timestamp in the variable str as well as the formatting mask to use in the variable fmt. The result will be stored in the variable that d points to.
If the formatting mask fmt is NULL, the function will fall back to the default formatting mask which is %Y-%m-%d %H:%M:%S.
This is the reverse function to PGTYPEStimestamp_fmt_asc. See the documentation there in order to find out about the possible formatting mask entries.

PGTYPEStimestamp_add_interval
Add an interval variable to a timestamp variable.
int PGTYPEStimestamp_add_interval(timestamp *tin, interval *span, timestamp *tout);
The function receives a pointer to a timestamp variable tin and a pointer to an interval variable span. It adds the interval to the timestamp and saves the resulting timestamp in the variable that tout points to.
Upon success, the function returns 0 and a negative value if an error occurred.

PGTYPEStimestamp_sub_interval
Subtract an interval variable from a timestamp variable.
int PGTYPEStimestamp_sub_interval(timestamp *tin, interval *span, timestamp *tout);
The function subtracts the interval variable that span points to from the timestamp variable that tin points to and saves the result into the variable that tout points to.
Upon success, the function returns 0 and a negative value if an error occurred.

### 32.8.4. The interval type

The interval type in C enables your programs to deal with data of the SQL type interval. See Section 8.5 for the equivalent type in the PostgreSQL server.

The following functions can be used to work with the interval type:

- **PGTYPESinterval_new**
  
  Return a pointer to a newly allocated interval variable.
  
  ```c
  interval *PGTYPESinterval_new(void);
  ```

- **PGTYPESinterval_free**
  
  Release the memory of a previously allocated interval variable.
  
  ```c
  void PGTYPESinterval_new(interval *intvl);
  ```

- **PGTYPESinterval_from_asc**
  
  Parse an interval from its textual representation.
  
  ```c
  interval *PGTYPESinterval_from_asc(char *str, char **endptr);
  ```

  The function parses the input string `str` and returns a pointer to an allocated interval variable. At the moment ecpg always parses the complete string and so it currently does not support to store the address of the first invalid character in `endptr`. You can safely set `endptr` to `NULL`.

- **PGTYPESinterval_to_asc**
  
  Convert a variable of type interval to its textual representation.
  
  ```c
  char *PGTYPESinterval_to_asc(interval *span);
  ```

  The function converts the interval variable that `span` points to into a C char*. The output looks like this example: @ 1 day 12 hours 59 mins 10 secs.

- **PGTYPESinterval_copy**
  
  Copy a variable of type interval.
  
  ```c
  int PGTYPESinterval_copy(interval *intvlsrc, interval *intvldest);
  ```

  The function copies the interval variable that `intvlsrc` points to into the variable that `intvldest` points to. Note that you need to allocate the memory for the destination variable before.

### 32.8.5. The decimal type

The decimal type is similar to the numeric type. However it is limited to a maximal precision of 30 significant digits. In contrast to the numeric type which can be created on the heap only, the decimal type can be created either on the stack or on the heap (by means of the functions **PGTYPESdecimal_new()** and **PGTYPESdecimal_free()**). There are a lot of other functions that deal with the decimal type in the Informix compatibility mode described in Section 32.9.

The following functions can be used to work with the decimal type and are not only contained in the `libcompat` library.
Chapter 32. ECPG - Embedded SQL in C

PGTYPESdecimal_new
   Request a pointer to a newly allocated decimal variable.
   
   decimal *PGTYPESdecimal_new(void);

PGTYPESdecimal_free
   Free a decimal type, release all of its memory.
   
   void PGTYPESdecimal_free(decimal *var);

32.8.6. errno values of pgtypeslib

PGTYPES_NUM_BAD_NUMERIC
   An argument should contain a numeric variable (or point to a numeric variable) but in fact its
   in-memory representation was invalid.

PGTYPES_NUM_OVERFLOW
   An overflow occurred. Since the numeric type can deal with almost arbitrary precision, convert-
   ing a numeric variable into other types might cause overflow.

PGTYPES_NUM_OVERFLOW
   An underflow occurred. Since the numeric type can deal with almost arbitrary precision, con-
   verting a numeric variable into other types might cause underflow.

PGTYPES_NUM_DIVIDE_ZERO
   A division by zero has been attempted.

PGTYPES_DATE_BAD_DATE

PGTYPES_DATE_ERR_EARGS

PGTYPES_DATE_ERR_ENOSHORTDATE

PGTYPES_DATE_ERR_ENOTDMY

PGTYPES_DATE_BAD_DAY

PGTYPES_DATE_BAD_MONTH

PGTYPES_DATE_BAD_DATE

PGTYPES_TS_BAD_TIMESTAMP

32.8.7. Special constants of pgtypeslib

PGTYPESInvalidTimestamp
   A value of type timestamp representing an invalid time stamp. This is returned by the function
   PGTYPEStimestamp_from_asc on parse error. Note that due to the internal representation of
the timestamp datatype, `PGTYPESInvalidTimestamp` is also a valid timestamp at the same time. It is set to 1899-12-31 23:59:59. In order to detect errors, make sure that your application does not only test for `PGTYPESInvalidTimestamp` but also for `errno != 0` after each call to `PGTYPEStimestamp_from_asc`.

### 32.9. Informix compatibility mode

ecpg can be run in a so-called Informix compatibility mode. If this mode is active, it tries to behave as if it were the Informix precompiler for Informix E/SQL. Generally spoken this will allow you to use the dollar sign instead of the `EXEC SQL` primitive to introduce embedded SQL commands:

```
$int j = 3;
$CONNECT TO :dbname;
$CREATE TABLE test(i INT PRIMARY KEY, j INT);
$INSERT INTO test(i, j) VALUES (7, :j);
$COMMIT;
```

There are two compatibility modes: INFORMIX, INFORMIX_SE

When linking programs that use this compatibility mode, remember to link against `libcompat` that is shipped with ecpg.

Besides the previously explained syntactic sugar, the Informix compatibility mode ports some functions for input, output and transformation of data as well as embedded SQL statements known from E/SQL to ecpg.

Informix compatibility mode is closely connected to the pgtypeslib library of ecpg. pgtypeslib maps SQL data types to data types within the C host program and most of the additional functions of the Informix compatibility mode allow you to operate on those C host program types. Note however that the extent of the compatibility is limited. It does not try to copy Informix behaviour; it allows you to do more or less the same operations and gives you functions that have the same name and the same basic behavior but it is no drop-in replacement if you are using Informix at the moment. Moreover, some of the data types are different. For example, PostgreSQL’s datetime and interval types do not know about ranges like for example `YEAR TO MINUTE` so you won’t find support in ecpg for that either.

### 32.9.1. Additional embedded SQL statements

**CLOSE DATABASE**

This statement closes the current connection. In fact, this is a synonym for ecpg’s `DISCONNECT CURRENT`:

```
$CLOSE DATABASE;  /* close the current connection */
EXEC SQL CLOSE DATABASE;
```
### 32.9.2. Additional functions

#### decadd

Add two decimal type values.

```c
int decadd(decimal *arg1, decimal *arg2, decimal *sum);
```

The function receives a pointer to the first operand of type decimal (`arg1`), a pointer to the second operand of type decimal (`arg2`) and a pointer to a value of type decimal that will contain the sum (`sum`). On success, the function returns 0. ECPG_INFORMIX_NUM_OVERFLOW is returned in case of overflow and ECPG_INFORMIX_NUM_UNDERFLOW in case of underflow. -1 is returned for other failures and errno is set to the respective errno number of the pgtypeslib.

#### deccmp

Compare two variables of type decimal.

```c
int deccmp(decimal *arg1, decimal *arg2);
```

The function receives a pointer to the first decimal value (`arg1`), a pointer to the second decimal value (`arg2`) and returns an integer value that indicates which is the bigger value.

- 1, if the value that `arg1` points to is bigger than the value that `arg2` points to
- -1, if the value that `arg1` points to is smaller than the value that `arg2` points to
- 0, if the value that `arg1` points to and the value that `arg2` points to are equal

#### deccopy

Copy a decimal value.

```c
void deccopy(decimal *src, decimal *target);
```

The function receives a pointer to the decimal value that should be copied as the first argument (`src`) and a pointer to the target structure of type decimal (`target`) as the second argument.

#### deccvasc

Convert a value from its ASCII representation into a decimal type.

```c
int deccvasc(char *cp, int len, decimal *np);
```

The function receives a pointer to string that contains the string representation of the number to be converted (`cp`) as well as its length (`len`). `np` is a pointer to the decimal value that saves the result of the operation.

Valid formats are for example: `-2.794`, `+3.44`, `592.49E07` or `-32.84e-4`.

The function returns 0 on success. If overflow or underflow occurred, ECPG_INFORMIX_NUM_OVERFLOW or ECPG_INFORMIX_NUM_UNDERFLOW is returned. If the ASCII representation could not be parsed, ECPG_INFORMIX_BAD_NUMERIC is returned or ECPG_INFORMIX_BAD_EXPONENT if this problem occurred while parsing the exponent.

#### deccvdbl

Convert a value of type double to a value of type decimal.

```c
int deccvdbl(double dbl, decimal *np);
```

The function receives the variable of type double that should be converted as its first argument (`dbl`). As the second argument (`np`), the function receives a pointer to the decimal variable that should hold the result of the operation.

The function returns 0 on success and a negative value if the conversion failed.
deccvint

Convert a value of type int to a value of type decimal.

```c
int deccvint(int in, decimal *np);
```

The function receives the variable of type int that should be converted as its first argument (`in`). As the second argument (`np`), the function receives a pointer to the decimal variable that should hold the result of the operation.

The function returns 0 on success and a negative value if the conversion failed.

deccvlong

Convert a value of type long to a value of type decimal.

```c
int deccvlong(long lng, decimal *np);
```

The function receives the variable of type long that should be converted as its first argument (`lng`). As the second argument (`np`), the function receives a pointer to the decimal variable that should hold the result of the operation.

The function returns 0 on success and a negative value if the conversion failed.

decdiv

Divide two variables of type decimal.

```c
int decdiv(decimal *n1, decimal *n2, decimal *result);
```

The function receives pointers to the variables that are the first (`n1`) and the second (`n2`) operands and calculates `n1/n2`. `result` is a pointer to the variable that should hold the result of the operation.

On success, 0 is returned and a negative value if the division fails. If overflow or underflow occurred, the function returns ECPG_INFORMIX_NUM_OVERFLOW or ECPG_INFORMIX_NUM_UNDERFLOW respectively. If an attempt to divide by zero is observed, the function returns ECPG_INFORMIX_DIVIDE_ZERO.

decmul

Multiply two decimal values.

```c
int decmul(decimal *n1, decimal *n2, decimal *result);
```

The function receives pointers to the variables that are the first (`n1`) and the second (`n2`) operands and calculates `n1*n2`. `result` is a pointer to the variable that should hold the result of the operation.

On success, 0 is returned and a negative value if the multiplication fails. If overflow or underflow occurred, the function returns ECPG_INFORMIX_NUM_OVERFLOW or ECPG_INFORMIX_NUM_UNDERFLOW respectively.

decsub

Subtract one decimal value from another.

```c
int decsub(decimal *n1, decimal *n2, decimal *result);
```

The function receives pointers to the variables that are the first (`n1`) and the second (`n2`) operands and calculates `n1-n2`. `result` is a pointer to the variable that should hold the result of the operation.

On success, 0 is returned and a negative value if the subtraction fails. If overflow or underflow occurred, the function returns ECPG_INFORMIX_NUM_OVERFLOW or ECPG_INFORMIX_NUM_UNDERFLOW respectively.
dectoasc

Convert a variable of type decimal to its ASCII representation in a C char* string.

```c
int dectoasc(decimal *np, char *cp, int len, int right)
```

The function receives a pointer to a variable of type decimal (`np`) that it converts to its textual representation. `cp` is the buffer that should hold the result of the operation. The parameter `right` specifies, how many digits right of the decimal point should be included in the output. The result will be rounded to this number of decimal digits. Setting `right` to -1 indicates that all available decimal digits should be included in the output. If the length of the output buffer, which is indicated by `len` is not sufficient to hold the textual representation including the trailing NUL character, only a single * character is stored in the result and -1 is returned.

The function returns either -1 if the buffer `cp` was too small or `ECPG_INFORMIX_OUT_OF_MEMORY` if memory was exhausted.

dectodbl

Convert a variable of type decimal to a double.

```c
int dectodbl(decimal *np, double *dblp);
```

The function receives a pointer to the decimal value to convert (`np`) and a pointer to the double variable that should hold the result of the operation (`dblp`).

On success, 0 is returned and a negative value if the conversion failed.

dectoint

Convert a variable to type decimal to an integer.

```c
int dectoint(decimal *np, int *ip);
```

The function receives a pointer to the decimal value to convert (`np`) and a pointer to the integer variable that should hold the result of the operation (`ip`).

On success, 0 is returned and a negative value if the conversion failed. If an overflow occurred, `ECPG_INFORMIX_NUM_OVERFLOW` is returned.

Note that the `ecpg` implementation differs from the Informix implementation. Informix limits an integer to the range from -32767 to 32767, while the limits in the `ecpg` implementation depend on the architecture (`-INT_MAX .. INT_MAX`).

dectolong

Convert a variable to type decimal to a long integer.

```c
int dectolong(decimal *np, long *lngp);
```

The function receives a pointer to the decimal value to convert (`np`) and a pointer to the long variable that should hold the result of the operation (`lngp`).

On success, 0 is returned and a negative value if the conversion failed. If an overflow occurred, `ECPG_INFORMIX_NUM_OVERFLOW` is returned.

Note that the `ecpg` implementation differs from the Informix implementation. Informix limits a long integer to the range from -2,147,483,647 to 2,147,483,647, while the limits in the `ecpg` implementation depend on the architecture (`-LONG_MAX .. LONG_MAX`).

rdatestr

Converts a date to a C char* string.

```c
int rdatestr(date d, char *str);
```

The function receives two arguments, the first one is the date to convert (`d`) and the second one is a pointer to the target string. The output format is always `yyyy-mm-dd`, so you need to allocate at least 11 bytes (including the NUL-terminator) for the string.
The function returns 0 on success and a negative value in case of error.

Note that ecpg’s implementation differs from the Informix implementation. In Informix the format can be influenced by setting environment variables. In ecpg however, you cannot change the output format.

rstrdate
Parse the textual representation of a date.

```c
int rstrdate(char *str, date *d);
```
The function receives the textual representation of the date to convert (str) and a pointer to a variable of type date (d). This function does not allow you to specify a format mask. It uses the default format mask of Informix which is mm/dd/yyyy. Internally, this function is implemented by means of rdefmtdate. Therefore, rstrdate is not faster and if you have the choice you should opt for rdefmtdate which allows you to specify the format mask explicitly.

The function returns the same values as rdefmtdate.

rtoday
Get the current date.

```c
void rtoday(date *d);
```
The function receives a pointer to a date variable (d) that it sets to the current date.

Internally this function uses the PGTYPESdate_today function.

rjulmdy
Extract the values for the day, the month and the year from a variable of type date.

```c
int rjulmdy(date d, short mdy[3]);
```
The function receives the date d and a pointer to an array of 3 short integer values mdy. The variable name indicates the sequential order: mdy[0] will be set to contain the number of the month, mdy[1] will be set to the value of the day and mdy[2] will contain the year.

The function always returns 0 at the moment.

Internally the function uses the PGTYPESdate_julmdy function.

rdefmtdate
Use a format mask to convert a character string to a value of type date.

```c
int rdefmtdate(date *d, char *fmt, char *str);
```
The function receives a pointer to the date value that should hold the result of the operation (d), the format mask to use for parsing the date (fmt) and the C char* string containing the textual representation of the date (str). The textual representation is expected to match the format mask. However you do not need to have a 1:1 mapping of the string to the format mask. The function only analyzes the sequential order and looks for the literals yy or yyyy that indicate the position of the year, mm to indicate the position of the month and dd to indicate the position of the day.

The function returns the following values:

- 0 - The function terminated successfully.
- ECPG_INFORMIX_ENOSHORTDATE - The date does not contain delimiters between day, month and year. In this case the input string must be exactly 6 or 8 bytes long but isn’t.
- ECPG_INFORMIX_ENOTDMY - The format string did not correctly indicate the sequential order of year, month and day.
- ECPG_INFORMIX_BAD_DAY - The input string does not contain a valid day.
- ECPG_INFORMIX_BAD_MONTH - The input string does not contain a valid month.
Chapter 32. ECPG - Embedded SQL in C

- ECPG_INFORMIX_BAD_YEAR - The input string does not contain a valid year.

Internally this function is implemented to use the `PGTYPESdate_defmt_asc` function. See the reference there for a table of example input.

rfmtdate
Convert a variable of type date to its textual representation using a format mask.

```c
int rfmtdate(date d, char *fmt, char *str);
```

The function receives the date to convert (`d`), the format mask (`fmt`) and the string that will hold the textual representation of the date (`str`).

On success, 0 is returned and a negative value if an error occurred.

Internally this function uses the `PGTYPESdate_fmt_asc` function, see the reference there for examples.

rmdyjul
Create a date value from an array of 3 short integers that specify the day, the month and the year of the date.

```c
int rmdyjul(short mdy[3], date *d);
```

The function receives the array of the 3 short integers (`mdy`) and a pointer to a variable of type `date` that should hold the result of the operation.

Currently the function returns always 0.

Internally the function is implemented to use the function `PGTYPESdate_mdyjul`.

rdayofweek
Return a number representing the day of the week for a date value.

```c
int rdayofweek(date d);
```

The function receives the date variable `d` as its only argument and returns an integer that indicates the day of the week for this date.

- 0 - Sunday
- 1 - Monday
- 2 - Tuesday
- 3 - Wednesday
- 4 - Thursday
- 5 - Friday
- 6 - Saturday

Internally the function is implemented to use the function `PGTYPESdate_dayofweek`.

dtcurrent
Retrieve the current timestamp.

```c
void dtcurrent(timestamp *ts);
```

The function retrieves the current timestamp and saves it into the timestamp variable that `ts` points to.
Chapter 32. ECPG - Embedded SQL in C

**dtcvasc**

Parses a timestamp from its textual representation in ANSI standard into a timestamp variable.

```c
int dtcvasc(char *str, timestamp *ts);
```

The function receives the string to parse (`str`) and a pointer to the timestamp variable that should hold the result of the operation (`ts`).

The function returns 0 on success and a negative value in case of error.

Internally this function uses the `PGTYPEStimestamp_from_asc` function. See the reference there for a table with example inputs.

**dtcvfmtasc**

Parses a timestamp from its textual representation in ANSI standard using a format mask into a timestamp variable.

```c
dtcvfmtasc(char *inbuf, char *fmtstr, timestamp *dtvalue)
```

The function receives the string to parse (`inbuf`), the format mask to use (`fmtstr`) and a pointer to the timestamp variable that should hold the result of the operation (`ts`).

This function is implemented by means of the `PGTYPEStimestamp_defmt_asc`. See the documentation there for a list of format specifiers that can be used.

The function returns 0 on success and a negative value in case of error.

**dtsub**

Subtract one timestamp from another and return a variable of type interval.

```c
int dtsub(timestamp *ts1, timestamp *ts2, interval *iv);
```

The function will subtract the timestamp variable that `ts2` points to from the timestamp variable that `ts1` points to and will store the result in the interval variable that `iv` points to.

Upon success, the function returns 0 and a negative value if an error occurred.

**dttoasc**

Convert a timestamp variable to a C char* string.

```c
int dttoasc(timestamp *ts, char *output);
```

The function receives a pointer to the timestamp variable to convert (`ts`) and the string that should hold the result of the operation (`output`). It converts `ts` to its textual representation in the ANSI SQL standard which is defined to be `YYYY-MM-DD HH:MM:SS`.

Upon success, the function returns 0 and a negative value if an error occurred.

**dttofmtasc**

Convert a timestamp variable to a C char* using a format mask.

```c
int dttofmtasc(timestamp *ts, char *output, int str_len, char *fmtstr);
```

The function receives a pointer to the timestamp variable to convert as its first argument (`ts`), a pointer to the output buffer (`output`), the maximal length that has been allocated for the output buffer (`str_len`) and the format mask to use for the conversion (`fmtstr`).

Upon success, the function returns 0 and a negative value if an error occurred.

Internally, this function uses the `PGTYPEStimestamp_fmt_asc` function. See the reference there for information on what format mask specifiers can be used.

**intoasc**

Convert an interval variable to a C char* string.

```c
int intoasc(interval *i, char *str);
```
The function receives a pointer to the interval variable to convert (i) and the string that should hold the result of the operation str). It converts i to its textual representation in the ANSI SQL standard which is defined to be YYYY-MM-DD HH:MM:SS.

Upon success, the function returns 0 and a negative value if an error occurred.

\textbf{rfmtlong}

Convert a long integer value to its textual representation using a format mask.

\begin{verbatim}
int rfmtlong(long lng_val, char *fmt, char *outbuf);
\end{verbatim}

The function receives the long value lng_val, the format mask fmt and a pointer to the output buffer outbuf. It converts the long value according to the format mask to its textual representation.

The format mask can be composed of the following format specifying characters:

\begin{itemize}
  \item * (asterisk) - if this position would be blank otherwise, fill it with an asterisk.
  \item & (ampersand) - if this position would be blank otherwise, fill it with a zero.
  \item # - turn leading zeroes into blanks.
  \item < - left-justify the number in the string.
  \item , (comma) - group numbers of four or more digits into groups of three digits separated by a comma.
  \item . (period) - this character separates the whole-number part of the number from the fractional part.
  \item - (minus) - the minus sign appears if the number is a negative value.
  \item + (plus) - the plus sign appears if the number is a positive value.
  \item ( - this replaces the minus sign in front of the negative number. The minus sign will not appear.
  \item ) - this character replaces the minus and is printed behind the negative value.
  \item $ - the currency symbol.
\end{itemize}

\textbf{rupshift}

Convert a string to upper case.

\begin{verbatim}
void rupshift(char *str);
\end{verbatim}

The function receives a pointer to the string and transforms every lower case character to upper case.

\textbf{byleng}

Return the number of characters in a string without counting trailing blanks.

\begin{verbatim}
int byleng(char *str, int len);
\end{verbatim}

The function expects a fixed-length string as its first argument (str) and its length as its second argument (len). It returns the number of significant characters, that is the length of the string without trailing blanks.

\textbf{ldchar}

Copy a fixed-length string into a null-terminated string.

\begin{verbatim}
void ldchar(char *src, int len, char *dest);
\end{verbatim}

The function receives the fixed-length string to copy (src), its length (len) and a pointer to the destination memory (dest). Note that you need to reserve at least len+1 bytes for the string.
that dest points to. The function copies at most len bytes to the new location (less if the source string has trailing blanks) and adds the null-terminator.

\[ \text{rgetmsg} \]

int rgetmsg(int msgnum, char *s, int maxsize);
This function exists but is not implemented at the moment!

\[ \text{rtypalign} \]

int rtypalign(int offset, int type);
This function exists but is not implemented at the moment!

\[ \text{rtypmsize} \]

int rtypmsize(int type, int len);
This function exists but is not implemented at the moment!

\[ \text{rtypwidth} \]

int rtypwidth(int sqltype, int sqllen);
This function exists but is not implemented at the moment!

\[ \text{rsetnull} \]

Set a variable to NULL.
int rsetnull(int t, char *ptr);
The function receives an integer that indicates the type of the variable and a pointer to the variable itself that is casted to a C char* pointer.

The following types exist:
- CCHARTYPE - For a variable of type char or char*
- CSHORTTYPE - For a variable of type short int
- CINTTYPE - For a variable of type int
- CBOOLTYPE - For a variable of type boolean
- CFLOATTYPE - For a variable of type float
- CLONGTYPE - For a variable of type long
- CDOUBLETYPE - For a variable of type double
- CDECIMALTYPE - For a variable of type decimal
- CDATETYPE - For a variable of type date
- CDTIMETYPE - For a variable of type timestamp

Here is an example of a call to this function:

```c
$char c[] = "abc \n";
$short s = 17;
$int i = -74874;

rsetnull(CCHARTYPE, (char *) c);
rsetnull(CSHORTTYPE, (char *) &s);
rsetnull(CINTTYPE, (char *) &i);
```
risnull

Test if a variable is NULL.

```c
int risnull(int t, char *ptr);
```

The function receives the type of the variable to test (t) as well a pointer to this variable (ptr). Note that the latter needs to be casted to a char*. See the function `rsetnull` for a list of possible variable types.

Here is an example of how to use this function:

```c
$char c[] = "abc ";
$short s = 17;
<int i = -74874;

risnull(CCHARTYPE, (char *) c);
risnull(CSHORTTYPE, (char *) &s);
risnull(CINTTYPE, (char *) &i);
```

### 32.9.3. Additional constants

Note that all constants here describe errors and all of them are defined to represent negative values. In the descriptions of the different constants you can also find the value that the constants represent in the current implementation. However you should not rely on this number. You can however rely on the fact all of them are defined to represent negative values.

- **ECPG_INFORMIX_NUM_OVERFLOW**
  
  Functions return this value if an overflow occurred in a calculation. Internally it is defined to -1200 (the Informix definition).

- **ECPG_INFORMIX_NUM_UNDERFLOW**
  
  Functions return this value if an underflow occurred in a calculation. Internally it is defined to -1201 (the Informix definition).

- **ECPG_INFORMIX_DIVIDE_ZERO**
  
  Functions return this value if an attempt to divide by zero is observed. Internally it is defined to -1202 (the Informix definition).

- **ECPG_INFORMIX_BAD_YEAR**
  
  Functions return this value if a bad value for a year was found while parsing a date. Internally it is defined to -1204 (the Informix definition).

- **ECPG_INFORMIX_BAD_MONTH**
  
  Functions return this value if a bad value for a month was found while parsing a date. Internally it is defined to -1205 (the Informix definition).

- **ECPG_INFORMIX_BAD_DAY**
  
  Functions return this value if a bad value for a day was found while parsing a date. Internally it is defined to -1206 (the Informix definition).

- **ECPG_INFORMIX_ENOSHORTDATE**
  
  Functions return this value if a parsing routine needs a short date representation but did not get the date string in the right length. Internally it is defined to -1209 (the Informix definition).
Chapter 32. ECPG - Embedded SQL in C

32.10. Using SQL Descriptor Areas

An SQL descriptor area is a more sophisticated method for processing the result of a SELECT or FETCH statement. An SQL descriptor area groups the data of one row of data together with metadata items into one data structure. The metadata is particularly useful when executing dynamic SQL statements, where the nature of the result columns might not be known ahead of time.

An SQL descriptor area consists of a header, which contains information concerning the entire descriptor, and one or more item descriptor areas, which basically each describe one column in the result row.

Before you can use an SQL descriptor area, you need to allocate one:

EXEC SQL ALLOCATE DESCRIPTOR identifier;

The identifier serves as the “variable name” of the descriptor area. When you don’t need the descriptor anymore, you should deallocate it:

EXEC SQL DEALLOCATE DESCRIPTOR identifier;

To use a descriptor area, specify it as the storage target in an INTO clause, instead of listing host variables:
EXEC SQL FETCH NEXT FROM mycursor INTO DESCRIPTOR mydesc;

Now how do you get the data out of the descriptor area? You can think of the descriptor area as a structure with named fields. To retrieve the value of a field from the header and store it into a host variable, use the following command:

EXEC SQL GET DESCRIPTOR name :hostvar = field;

Currently, there is only one header field defined: COUNT, which tells how many item descriptor areas exist (that is, how many columns are contained in the result). The host variable needs to be of an integer type. To get a field from the item descriptor area, use the following command:

EXEC SQL GET DESCRIPTOR name VALUE num :hostvar = field;

num can be a literal integer or a host variable containing an integer. Possible fields are:

CARDINALITY (integer)
   number of rows in the result set

DATA
   actual data item (therefore, the data type of this field depends on the query)

DATETIME_INTERVAL_CODE (integer)
   not implemented

DATETIME_INTERVAL_PRECISION (integer)
   not implemented

INDICATOR (integer)
   the indicator (indicating a null value or a value truncation)

KEY_MEMBER (integer)
   not implemented

LENGTH (integer)
   length of the datum in characters

NAME (string)
   name of the column

NULLABLE (integer)
   not implemented

OCTET_LENGTH (integer)
   length of the character representation of the datum in bytes

PRECISION (integer)
   precision (for type numeric)

RETURNED_LENGTH (integer)
   length of the datum in characters
32.11. Error Handling

This section describes how you can handle exceptional conditions and warnings in an embedded SQL program. There are several nonexclusive facilities for this.

32.11.1. Setting Callbacks

One simple method to catch errors and warnings is to set a specific action to be executed whenever a particular condition occurs. In general:

EXEC SQL WHENEVER condition action;

*condition* can be one of the following:

- **SQLERROR**
  The specified action is called whenever an error occurs during the execution of an SQL statement.

- **SQLWARNING**
  The specified action is called whenever a warning occurs during the execution of an SQL statement.

- **NOT FOUND**
  The specified action is called whenever an SQL statement retrieves or affects zero rows. (This condition is not an error, but you might be interested in handling it specially.)

*action* can be one of the following:

- **CONTINUE**
  This effectively means that the condition is ignored. This is the default.

- **GOTO label**

  Jump to the specified label (using a C goto statement).

- **SQLPRINT**

  Print a message to standard error. This is useful for simple programs or during prototyping. The details of the message cannot be configured.
STOP

Call `exit(1)`, which will terminate the program.

DO BREAK

Execute the C statement `break`. This should only be used in loops or `switch` statements.

CALL `name (args)`
DO `name (args)`

Call the specified C functions with the specified arguments.

The SQL standard only provides for the actions `CONTINUE` and `GOTO` (and `GO TO`).

Here is an example that you might want to use in a simple program. It prints a simple message when a warning occurs and aborts the program when an error happens:

```sql
EXEC SQL WHENEVER SQLWARNING SQLPRINT;
EXEC SQL WHENEVER SQLERROR STOP;
```

The statement `EXEC SQL WHENEVER` is a directive of the SQL preprocessor, not a C statement. The error or warning actions that it sets apply to all embedded SQL statements that appear below the point where the handler is set, unless a different action was set for the same condition between the first `EXEC SQL WHENEVER` and the SQL statement causing the condition, regardless of the flow of control in the C program. So neither of the two following C program excerpts will have the desired effect:

```c
/*
 * WRONG
 */
int main(int argc, char *argv[])
{
    ...
    if (verbose) {
        EXEC SQL WHENEVER SQLWARNING SQLPRINT;
    }
    ...
    EXEC SQL SELECT ...;
    ...
}
```

```c
/*
 * WRONG
 */
int main(int argc, char *argv[])
{
    ...
    set_error_handler();
    ...
    EXEC SQL SELECT ...;
    ...
}
```

```c
static void set_error_handler(void)
{
    EXEC SQL WHENEVER SQLERROR STOP;
}
```
32.11.2. sqlca

For more powerful error handling, the embedded SQL interface provides a global variable with the name sqlca that has the following structure:

```c
struct {
    char sqlcaid[8];
    long sqlabc;
    long sqlcode;
    struct {
        int sqlerrml;
        char sqlerrmc[70];
    } sqlerrm;
    char sqlerrp[8];
    long sqlerrd[6];
    char sqlwarn[8];
    char sqlstate[5];
} sqlca;
```

(In a multithreaded program, every thread automatically gets its own copy of sqlca. This works similarly to the handling of the standard C global variable errno.)

sqlca covers both warnings and errors. If multiple warnings or errors occur during the execution of a statement, then sqlca will only contain information about the last one.

If no error occurred in the last SQL statement, sqlca.sqlcode will be 0 and sqlca.sqlstate will be "00000". If a warning or error occurred, then sqlca.sqlcode will be negative and sqlca.sqlstate will be different from "00000". A positive sqlca.sqlcode indicates a harmless condition, such as that the last query returned zero rows. sqlcode and sqlstate are two different error code schemes; details appear below.

If the last SQL statement was successful, then sqlca.sqlerrd[1] contains the OID of the processed row, if applicable, and sqlca.sqlerrd[2] contains the number of processed or returned rows, if applicable to the command.

In case of an error or warning, sqlca.sqlerrm.sqlerrmc will contain a string that describes the error. The field sqlca.sqlerrm.sqlerrml contains the length of the error message that is stored in sqlca.sqlerrm.sqlerrmc (the result of strlen()), not really interesting for a C programmer). Note that some messages are too long to fit in the fixed-size sqlerrmc array; they will be truncated.

In case of a warning, sqlca.sqlwarn[2] is set to W. (In all other cases, it is set to something different from W.) If sqlca.sqlwarn[1] is set to W, then a value was truncated when it was stored in a host variable. sqlca.sqlwarn[0] is set to W if any of the other elements are set to indicate a warning.

The fields sqlcaid, sqlcabc, sqlerrp, and the remaining elements of sqlerrd and sqlwarn currently contain no useful information.

The structure sqlca is not defined in the SQL standard, but is implemented in several other SQL database systems. The definitions are similar at the core, but if you want to write portable applications, then you should investigate the different implementations carefully.

32.11.3. SQLSTATE vs SQLCODE

The fields sqlca.sqlstate and sqlca.sqlcode are two different schemes that provide error codes. Both are derived from the SQL standard, but SQLCODE has been marked deprecated in the
SQL-92 edition of the standard and has been dropped in later editions. Therefore, new applications are strongly encouraged to use SQLSTATE.

SQLSTATE is a five-character array. The five characters contain digits or upper-case letters that represent codes of various error and warning conditions. SQLSTATE has a hierarchical scheme: the first two characters indicate the general class of the condition, the last three characters indicate a subclass of the general condition. A successful state is indicated by the code 00000. The SQLSTATE codes are for the most part defined in the SQL standard. The PostgreSQL server natively supports SQLSTATE error codes; therefore a high degree of consistency can be achieved by using this error code scheme throughout all applications. For further information see Appendix A.

SQLCODE, the deprecated error code scheme, is a simple integer. A value of 0 indicates success, a positive value indicates success with additional information, a negative value indicates an error. The SQL standard only defines the positive value +100, which indicates that the last command returned or affected zero rows, and no specific negative values. Therefore, this scheme can only achieve poor portability and does not have a hierarchical code assignment. Historically, the embedded SQL processor for PostgreSQL has assigned some specific SQLCODE values for its use, which are listed below with their numeric value and their symbolic name. Remember that these are not portable to other SQL implementations. To simplify the porting of applications to the SQLSTATE scheme, the corresponding SQLSTATE is also listed. There is, however, no one-to-one or one-to-many mapping between the two schemes (indeed it is many-to-many), so you should consult the global SQLSTATE listing in Appendix A in each case.

These are the assigned SQLCODE values:

-12 (ECPG_OUT_OF_MEMORY)
   Indicates that your virtual memory is exhausted. (SQLSTATE YE001)

-200 (ECPG_UNSUPPORTED)
   Indicates the preprocessor has generated something that the library does not know about. Perhaps you are running incompatible versions of the preprocessor and the library. (SQLSTATE YE002)

-201 (ECPG_TOO_MANY_ARGUMENTS)
   This means that the command specified more host variables than the command expected. (SQLSTATE 07001 or 07002)

-202 (ECPG_TOO_FEW_ARGUMENTS)
   This means that the command specified fewer host variables than the command expected. (SQLSTATE 07001 or 07002)

-203 (ECPG_TOO_MANY_MATCHES)
   This means a query has returned multiple rows but the statement was only prepared to store one result row (for example, because the specified variables are not arrays). (SQLSTATE 21000)

-204 (ECPG_INT_FORMAT)
   The host variable is of type int and the datum in the database is of a different type and contains a value that cannot be interpreted as an int. The library uses strtol() for this conversion. (SQLSTATE 42804)

-205 (ECPG_UINT_FORMAT)
   The host variable is of type unsigned int and the datum in the database is of a different type and contains a value that cannot be interpreted as an unsigned int. The library uses strtoul() for this conversion. (SQLSTATE 42804)
The host variable is of type `float` and the datum in the database is of another type and contains a value that cannot be interpreted as a `float`. The library uses `strtod()` for this conversion. (SQLSTATE 42804)

This means the host variable is of type `bool` and the datum in the database is neither `'t'` nor `'f'`. (SQLSTATE 42804)

The statement sent to the PostgreSQL server was empty. (This cannot normally happen in an embedded SQL program, so it might point to an internal error.) (SQLSTATE YE002)

A null value was returned and no null indicator variable was supplied. (SQLSTATE 22002)

An ordinary variable was used in a place that requires an array. (SQLSTATE 42804)

The database returned an ordinary variable in a place that requires array value. (SQLSTATE 42804)

The program tried to access a connection that does not exist. (SQLSTATE 08003)

The program tried to access a connection that does exist but is not open. (This is an internal error.) (SQLSTATE YE002)

The statement you are trying to use has not been prepared. (SQLSTATE 26000)

The descriptor specified was not found. The statement you are trying to use has not been prepared. (SQLSTATE 33000)

The descriptor index specified was out of range. (SQLSTATE 07009)

An invalid descriptor item was requested. (This is an internal error.) (SQLSTATE YE002)

During the execution of a dynamic statement, the database returned a numeric value and the host variable was not numeric. (SQLSTATE 07006)

During the execution of a dynamic statement, the database returned a non-numeric value and the host variable was numeric. (SQLSTATE 07006)

Some error caused by the PostgreSQL server. The message contains the error message from the PostgreSQL server.
The PostgreSQL server signaled that we cannot start, commit, or rollback the transaction. (SQLSTATE 08007)

The connection attempt to the database did not succeed. (SQLSTATE 08001)

This is a harmless condition indicating that the last command retrieved or processed zero rows, or that you are at the end of the cursor. (SQLSTATE 02000)

### 32.12. Preprocessor directives

#### 32.12.1. Including files

To include an external file into your embedded SQL program, use:

```sql
EXEC SQL INCLUDE filename;
```

The embedded SQL preprocessor will look for a file named `filename.h`, preprocess it, and include it in the resulting C output. Thus, embedded SQL statements in the included file are handled correctly.

Note that this is **not** the same as:

```c
#include <filename.h>
```

because this file would not be subject to SQL command preprocessing. Naturally, you can continue to use the C `#include` directive to include other header files.

**Note:** The include file name is case-sensitive, even though the rest of the `EXEC SQL INCLUDE` command follows the normal SQL case-sensitivity rules.

#### 32.12.2. The `#define` and `#undef` directives

Similar to the directive `#define` that is known from C, embedded SQL has a similar concept:

```sql
EXEC SQL DEFINE name;
EXEC SQL DEFINE name value;
```

So you can define a name:

```sql
EXEC SQL DEFINE HAVE_FEATURE;
```

And you can also define constants:

```sql
EXEC SQL DEFINE MYNUMBER 12;
EXEC SQL DEFINE MYSTRING 'abc';
```
Use `undef` to remove a previous definition:

```c
EXEC SQL UNDEF MYNUMBER;
```

Of course you can continue to use the C versions `#define` and `#undef` in your embedded SQL program. The difference is where your defined values get evaluated. If you use `EXEC SQL DEFINE` then the ecpg preprocessor evaluates the defines and substitutes the values. For example if you write:

```c
EXEC SQL DEFINE MYNUMBER 12;
...
EXEC SQL UPDATE Tbl SET col = MYNUMBER;
```

then ecpg will already do the substitution and your C compiler will never see any name or identifier `MYNUMBER`. Note that you cannot use `#define` for a constant that you are going to use in an embedded SQL query because in this case the embedded SQL precompiler is not able to see this declaration.

### 32.12.3. ifdef, ifndef, else, elif and endif directives

You can use the following directives to compile code sections conditionally:

```c
EXEC SQL ifdef name;

Checks a `name` and processes subsequent lines if `name` has been created with `EXEC SQL define name`.

EXEC SQL ifndef name;

Checks a `name` and processes subsequent lines if `name` has not been created with `EXEC SQL define name`.

EXEC SQL else;

Starts processing an alternative section to a section introduced by either `EXEC SQL ifdef name` or `EXEC SQL ifndef name`.

EXEC SQL elif name;

Checks `name` and starts an alternative section if `name` has been created with `EXEC SQL define name`.

EXEC SQL endif;

Ends an alternative section.

Example:

```c
exec sql ifdef TZVAR;
exec sql SET TIMEZONE TO 'GMT';
exec sql elif TZNAME;
exec sql SET TIMEZONE TO TZNAME;
exec sql else;
exec sql SET TIMEZONE TO TZVAR;
exec sql endif;
```
32.13. Processing Embedded SQL Programs

Now that you have an idea how to form embedded SQL C programs, you probably want to know how to compile them. Before compiling you run the file through the embedded SQL C preprocessor, which converts the SQL statements you used to special function calls. After compiling, you must link with a special library that contains the needed functions. These functions fetch information from the arguments, perform the SQL command using the libpq interface, and put the result in the arguments specified for output.

The preprocessor program is called ecpg and is included in a normal PostgreSQL installation. Embedded SQL programs are typically named with an extension .pgc. If you have a program file called progl.pgc, you can preprocess it by simply calling:

ecpg progl.pgc

This will create a file called progl.c. If your input files do not follow the suggested naming pattern, you can specify the output file explicitly using the -o option.

The preprocessed file can be compiled normally, for example:

cc -c progl.c

The generated C source files include header files from the PostgreSQL installation, so if you installed PostgreSQL in a location that is not searched by default, you have to add an option such as -I/usr/local/pgsql/include to the compilation command line.

To link an embedded SQL program, you need to include the libecpg library, like so:

cc -o myprog prog1.o prog2.o ... -lepg

Again, you might have to add an option like -L/usr/local/pgsql/lib to that command line.

If you manage the build process of a larger project using make, it might be convenient to include the following implicit rule to your makefiles:

ECPG = ecpg
%.c: %.pgc
  $(ECPG) $<

The complete syntax of the ecpg command is detailed in ecpg.

The ecpg library is thread-safe if it is built using the --enable-thread-safety command-line option to configure. (You might need to use other threading command-line options to compile your client code.)

32.14. Library Functions

The libecpg library primarily contains “hidden” functions that are used to implement the functionality expressed by the embedded SQL commands. But there are some functions that can usefully be called directly. Note that this makes your code unportable.

- ECPGdebug(int on, FILE *stream) turns on debug logging if called with the first argument non-zero. Debug logging is done on stream. The log contains all SQL statements with all the
input variables inserted, and the results from the PostgreSQL server. This can be very useful when searching for errors in your SQL statements.

**Note:** On Windows, if the ecpg libraries and an application are compiled with different flags, this function call will crash the application because the internal representation of the `FILE` pointers differ. Specifically, multithreaded/single-threaded, release/debug, and static/dynamic flags should be the same for the library and all applications using that library.

- ECPGstatus(int lineno, const char* connection_name) returns true if you are connected to a database and false if not. `connection_name` can be NULL if a single connection is being used.

# 32.15. Internals

This section explains how ECPG works internally. This information can occasionally be useful to help users understand how to use ECPG.

The first four lines written by ecpg to the output are fixed lines. Two are comments and two are include lines necessary to interface to the library. Then the preprocessor reads through the file and writes output. Normally it just echoes everything to the output.

When it sees an `EXEC SQL` statement, it intervenes and changes it. The command starts with `EXEC` and ends with `;`. Everything in between is treated as an SQL statement and parsed for variable substitution.

Variable substitution occurs when a symbol starts with a colon (:). The variable with that name is looked up among the variables that were previously declared within a `EXEC SQL DECLARE` section.

The most important function in the library is `ECPGdo`, which takes care of executing most commands. It takes a variable number of arguments. This can easily add up to 50 or so arguments, and we hope this will not be a problem on any platform.

The arguments are:

**A line number**

This is the line number of the original line; used in error messages only.

**A string**

This is the SQL command that is to be issued. It is modified by the input variables, i.e., the variables that where not known at compile time but are to be entered in the command. Where the variables should go the string contains `?`.

**Input variables**

Every input variable causes ten arguments to be created. (See below.)

*ECPGt_EOIT*

An enum telling that there are no more input variables.

**Output variables**

Every output variable causes ten arguments to be created. (See below.) These variables are filled by the function.
ECPGt_EORT

An enum telling that there are no more variables.

For every variable that is part of the SQL command, the function gets ten arguments:

1. The type as a special symbol.
2. A pointer to the value or a pointer to the pointer.
3. The size of the variable if it is a char or varchar.
4. The number of elements in the array (for array fetches).
5. The offset to the next element in the array (for array fetches).
6. The type of the indicator variable as a special symbol.
7. A pointer to the indicator variable.
8. 0
9. The number of elements in the indicator array (for array fetches).
10. The offset to the next element in the indicator array (for array fetches).

Note that not all SQL commands are treated in this way. For instance, an open cursor statement like:

EXEC SQL OPEN cursor;

is not copied to the output. Instead, the cursor’s DECLARE command is used at the position of the OPEN command because it indeed opens the cursor.

Here is a complete example describing the output of the preprocessor of a file foo.pgc (details might change with each particular version of the preprocessor):

EXEC SQL BEGIN DECLARE SECTION;
int index;
int result;
EXEC SQL END DECLARE SECTION;
...
EXEC SQL SELECT res INTO :result FROM mytable WHERE index = :index;

is translated into:

/* Processed by ecpg (2.6.0) */
/* These two include files are added by the preprocessor */
#include <ecpgtype.h>;
#include <ecpglib.h>;

/* exec sql begin declare section */

#line 1 "foo.pgc"

int index;
int result;
/* exec sql end declare section */
...
ECPGdo(__LINE__, NULL, "SELECT res FROM mytable WHERE index = ? ", ECPGt_int,&(index),1L,1L,sizeof(int),
ECPGt_NO_INDICATOR, NULL, 0L, 0L, 0L, ECPGt_EDIT,
ECPGt_int, &(result), 1L, 1L, sizeof(int),
ECPGt_NO_INDICATOR, NULL, 0L, 0L, 0L, ECPGt_EORT);

#line 147 "foo.pgc"

(The indentation here is added for readability and not something the preprocessor does.)
Chapter 33. The Information Schema

The information schema consists of a set of views that contain information about the objects defined in the current database. The information schema is defined in the SQL standard and can therefore be expected to be portable and remain stable — unlike the system catalogs, which are specific to PostgreSQL and are modelled after implementation concerns. The information schema views do not, however, contain information about PostgreSQL-specific features; to inquire about those you need to query the system catalogs or other PostgreSQL-specific views.

33.1. The Schema

The information schema itself is a schema named information_schema. This schema automatically exists in all databases. The owner of this schema is the initial database user in the cluster, and that user naturally has all the privileges on this schema, including the ability to drop it (but the space savings achieved by that are minuscule).

By default, the information schema is not in the schema search path, so you need to access all objects in it through qualified names. Since the names of some of the objects in the information schema are generic names that might occur in user applications, you should be careful if you want to put the information schema in the path.

33.2. Data Types

The columns of the information schema views use special data types that are defined in the information schema. These are defined as simple domains over ordinary built-in types. You should not use these types for work outside the information schema, but your applications must be prepared for them if they select from the information schema.

These types are:

- cardinal_number
  A nonnegative integer.
- character_data
  A character string (without specific maximum length).
- sql_identifier
  A character string. This type is used for SQL identifiers, the type character_data is used for any other kind of text data.
- time_stamp
  A domain over the type timestamp with time zone

Every column in the information schema has one of these four types.

Boolean (true/false) data is represented in the information schema by a column of type character_data that contains either YES or NO. (The information schema was invented before the type boolean was added to the SQL standard, so this convention is necessary to keep the information schema backward compatible.)
33.3. information_schema_catalog_name

information_schema_catalog_name is a table that always contains one row and one column containing the name of the current database (current catalog, in SQL terminology).

Table 33-1. information_schema_catalog_name Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>catalog_name</td>
<td>sql_identifier</td>
<td>Name of the database that contains this information schema</td>
</tr>
</tbody>
</table>

33.4. administrable_role_authorizations

The view administrable_role_authorizations identifies all roles that the current user has the admin option for.

Table 33-2. administrable_role_authorizations Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>Name of the role to which this role membership was granted (can be the current user, or a different role in case of nested role memberships)</td>
</tr>
<tr>
<td>role_name</td>
<td>sql_identifier</td>
<td>Name of a role</td>
</tr>
<tr>
<td>is_grantable</td>
<td>character_data</td>
<td>Always YES</td>
</tr>
</tbody>
</table>

33.5. applicable_roles

The view applicable_roles identifies all roles whose privileges the current user can use. This means there is some chain of role grants from the current user to the role in question. The current user itself is also an applicable role. The set of applicable roles is generally used for permission checking.

Table 33-3. applicable_roles Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>Name of the role to which this role membership was granted (can be the current user, or a different role in case of nested role memberships)</td>
</tr>
<tr>
<td>role_name</td>
<td>sql_identifier</td>
<td>Name of a role</td>
</tr>
</tbody>
</table>
### 33.6. attributes

The view attributes contains information about the attributes of composite data types defined in the database. (Note that the view does not give information about table columns, which are sometimes called attributes in PostgreSQL contexts.)

**Table 33-4. attributes Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>

</table>

See also under Section 33.12, a similarly structured view, for further information on some of the columns.

### 33.7. check_constraint_routine_usage

The view `check_constraint_routine_usage` identifies routines (functions and procedures) that are used by a check constraint. Only those routines are shown that are owned by a currently enabled role.

**Table 33-5. check_constraint_routine_usage Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>constraint_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the constraint (always the current database)</td>
</tr>
</tbody>
</table>
### 33.8. check CONSTRAINTS

The view `check_constraints` contains all check constraints, either defined on a table or on a domain, that are owned by a currently enabled role. (The owner of the table or domain is the owner of the constraint.)

#### Table 33-6. check_constraints Columns

<table>
<thead>
<tr>

<td>sql_identifier</td>
<td>Name of the schema containing the domain</td>
</tr>
<tr>
<td>domain_name</td>
<td>sql_identifier</td>
<td>Name of the domain</td>
</tr>
</tbody>
</table>

586
### 33.10. column_privileges

The view `column_privileges` identifies all privileges granted on columns to a currently enabled role or by a currently enabled role. There is one row for each combination of column, grantor, and grantee.

In PostgreSQL, you can only grant privileges on entire tables, not individual columns. Therefore, this view contains the same information as `table_privileges`, just represented through one row for each column in each appropriate table, but it only covers privilege types where column granularity is possible: `SELECT`, `INSERT`, `UPDATE`, `REFERENCES`. If you want to make your applications fit for possible future developments, it is generally the right choice to use this view instead of `table_privileges` if one of those privilege types is concerned.

#### Table 33-8. column_privileges Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantor</td>
<td>sql_identifier</td>
<td>Name of the role that granted the privilege</td>
</tr>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>Name of the role that the privilege was granted to</td>
</tr>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table that contains the column (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table that contains the column</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table that contains the column</td>
</tr>
<tr>
<td>column_name</td>
<td>sql_identifier</td>
<td>Name of the column</td>
</tr>
<tr>

<td>character_data</td>
<td>Type of the privilege: <code>SELECT</code>, <code>INSERT</code>, <code>UPDATE</code>, <code>REFERENCES</code></td>
</tr>
<tr>
<td>is_grantable</td>
<td>character_data</td>
<td>YES if the privilege is grantable, NO if not</td>
</tr>
</tbody>
</table>
### 33.11. `column_udt_usage`

The view `column_udt_usage` identifies all columns that use data types owned by a currently enabled role. Note that in PostgreSQL, built-in data types behave like user-defined types, so they are included here as well. See also Section 33.12 for details.

**Table 33-9. `column_udt_usage` Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>udt_catalog</td>

<tr>
<td>is_updatable</td>
<td>character_data</td>
<td>YES if the column is updatable, NO if not (Columns in base tables are always updatable, columns in views not necessarily)</td>
</tr>
</tbody>
</table>

Since data types can be defined in a variety of ways in SQL, and PostgreSQL contains additional ways to define data types, their representation in the information schema can be somewhat difficult. The column `data_type` is supposed to identify the underlying built-in type of the column. In PostgreSQL, this means that the type is defined in the system catalog schema `pg_catalog`. This column might be useful if the application can handle the well-known built-in types specially (for example, format the numeric types differently or use the data in the precision columns). The columns `udt_name`, `udt_schema`, and `udt_catalog` always identify the underlying data type of the column, even if the column is based on a domain. (Since PostgreSQL treats built-in types like user-defined types, built-in types appear here as well. This is an extension of the SQL standard.) These columns should be used if an application wants to process data differently according to the type, because in that case it wouldn’t matter if the column is really based on a domain. If the column is based on a domain, the identity
of the domain is stored in the columns domain_name, domain_schema, and domain_catalog. If you want to pair up columns with their associated data types and treat domains as separate types, you could write \texttt{coalesce(domain_name, udt_name)}, etc.

### 33.13. \texttt{constraint_column_usage}

The view \texttt{constraint_column_usage} identifies all columns in the current database that are used by some constraint. Only those columns are shown that are contained in a table owned by a currently enabled role. For a check constraint, this view identifies the columns that are used in the check expression. For a foreign key constraint, this view identifies the columns that the foreign key references. For a unique or primary key constraint, this view identifies the constrained columns.

**Table 33-11. \texttt{constraint_column_usage} Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table that contains the column that is used by some constraint (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table that contains the column that is used by some constraint</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table that contains the column that is used by some constraint</td>
</tr>
<tr>
<td>column_name</td>
<td>sql_identifier</td>
<td>Name of the column that is used by some constraint</td>
</tr>
<tr>
<td>constraint_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the constraint (always the current database)</td>
</tr>
<tr>
<td>constraint_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the constraint</td>
</tr>
<tr>
<td>constraint_name</td>
<td>sql_identifier</td>
<td>Name of the constraint</td>
</tr>
</tbody>
</table>

### 33.14. \texttt{constraint_table_usage}

The view \texttt{constraint_table_usage} identifies all tables in the current database that are used by some constraint and are owned by a currently enabled role. (This is different from the view \texttt{table_constraints}, which identifies all table constraints along with the table they are defined on.) For a foreign key constraint, this view identifies the table that the foreign key references. For a unique or primary key constraint, this view simply identifies the table the constraint belongs to. Check constraints and not-null constraints are not included in this view.

**Table 33-12. \texttt{constraint_table_usage} Columns**
### 33.15. `data_type_privileges`

The view `data_type_privileges` identifies all data type descriptors that the current user has access to, by way of being the owner of the described object or having some privilege for it. A data type descriptor is generated whenever a data type is used in the definition of a table column, a domain, or a function (as parameter or return type) and stores some information about how the data type is used in that instance (for example, the declared maximum length, if applicable). Each data type descriptor is assigned an arbitrary identifier that is unique among the data type descriptor identifiers assigned for one object (table, domain, function). This view is probably not useful for applications, but it is used to define some other views in the information schema.

#### Table 33-13. `data_type_privileges` Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>object_catalog</td>
<td>sql_identifier</td>

<tr>
<td>object_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the described object</td>
</tr>
<tr>
<td>object_name</td>
<td>sql_identifier</td>
<td>Name of the described object</td>
</tr>
<tr>
<td>object_type</td>
<td>character_data</td>
<td>The type of the described object: one of TABLE (the data type descriptor pertains to a column of that table), DOMAIN (the data type descriptors pertains to that domain), ROUTINE (the data type descriptor pertains to a parameter or the return data type of that function).</td>
</tr>
</tbody>
</table>
### 33.16. domain_constraints

The view `domain_constraints` contains all constraints belonging to domains defined in the current database.

**Table 33-14. domain_constraints Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>constraint_catalog</td>
<td>sql_identifier</td>

</tr>
<tr>
<td>scope_name</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>maximum_cardinality</td>
<td>cardinal_number</td>
<td>Always null, because arrays always have unlimited maximum cardinality in PostgreSQL</td>
</tr>
<tr>
<td>dtd_identifier</td>
<td>sql_identifier</td>
<td>An identifier of the data type descriptor of the domain, unique among the data type descriptors pertaining to the domain (which is trivial, because a domain only contains one data type descriptor). This is mainly useful for joining with other instances of such identifiers. (The specific format of the identifier is not defined and not guaranteed to remain the same in future versions.)</td>
</tr>
</tbody>
</table>

### 33.19. element_types

The view element_types contains the data type descriptors of the elements of arrays. When a table column, domain, function parameter, or function return value is defined to be of an array type, the respective information schema view only contains ARRAY in the column data_type. To obtain information on the element type of the array, you can join the respective view with this view. For example, to show the columns of a table with data types and array element types, if applicable, you
could do:

```
SELECT c.column_name, c.data_type, e.data_type AS element_type
FROM information_schema.columns c LEFT JOIN information_schema.element_types e
  ON ((c.table_catalog, c.table_schema, c.table_name, 'TABLE', c.dtd_identifier)
    = (e.object_catalog, e.object_schema, e.object_name, e.object_type, e.collection_)
WHERE c.table_schema = '...' AND c.table_name = '...
ORDER BY c.ordinal_position;
```

This view only includes objects that the current user has access to, by way of being the owner or having some privilege.

### Table 33-17. `element_types` Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>object_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the object that uses the array being described (always the current database)</td>
</tr>
<tr>

<tr>
<td>udt_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that the data type of the elements is defined in (always the current database)</td>
</tr>
</tbody>
</table>
33.20. enabled_roles

The view enabled_roles identifies the currently “enabled roles”. The enabled roles are recursively defined as the current user together with all roles that have been granted to the enabled roles with automatic inheritance. In other words, these are all roles that the current user has direct or indirect, automatically inheriting membership in.

For permission checking, the set of “applicable roles” is applied, which can be broader than the set of enabled roles. So generally, it is better to use the view applicable_roles instead of this one; see also there.

Table 33-18. enabled_roles Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>role_name</td>
<td>sql_identifier</td>
<td>Name of a role</td>
</tr>
</tbody>
</table>

33.21. key_column_usage

The view key_column_usage identifies all columns in the current database that are restricted by some unique, primary key, or foreign key constraint. Check constraints are not included in this view. Only those columns are shown that the current user has access to, by way of being the owner or having some privilege.

Table 33-19. key_column_usage Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
### Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>constraint_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the constraint (always the current database)</td>
</tr>
<tr>
<td>constraint_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the constraint</td>
</tr>
<tr>
<td>constraint_name</td>
<td>sql_identifier</td>
<td>Name of the constraint</td>
</tr>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table that contains the column that is restricted by this constraint (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table that contains the column that is restricted by this constraint</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table that contains the column that is restricted by this constraint</td>
</tr>
<tr>
<td>column_name</td>
<td>sql_identifier</td>
<td>Name of the column that is restricted by this constraint</td>
</tr>
<tr>
<td>ordinal_position</td>
<td>cardinal_number</td>
<td>Ordinal position of the column within the constraint key (count starts at 1)</td>
</tr>
<tr>
<td>position_in_unique_constraint</td>
<td>cardinal_number</td>
<td>For a foreign-key constraint, ordinal position of the referenced column within its unique constraint (count starts at 1); otherwise null</td>
</tr>
</tbody>
</table>

#### 33.22. parameters

The view `parameters` contains information about the parameters (arguments) of all functions in the current database. Only those functions are shown that the current user has access to (by way of being the owner or having some privilege).

### Table 33-20. parameters Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>specific_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the function (always the current database)</td>
</tr>
<tr>
<td>specific_schema</td>
<td>sql_identifier</td>
<td>Name of the schema containing the function</td>
</tr>
<tr>
<td>specific_name</td>
<td>sql_identifier</td>
<td>The “specific name” of the function. See Section 33.29 for more information.</td>

<tr>
<td>scope_name</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>maximum_cardinality</td>
<td>cardinal_number</td>
<td>Always null, because arrays always have unlimited maximum cardinality in PostgreSQL</td>
</tr>
</tbody>
</table>
Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>dtd_identifier</td>
<td>sql_identifier</td>
<td>An identifier of the data type descriptor of the parameter, unique among the data type descriptors pertaining to the function. This is mainly useful for joining with other instances of such identifiers. (The specific format of the identifier is not defined and not guaranteed to remain the same in future versions.)</td>
</tr>
</tbody>
</table>

### 33.23. referential_constraints

The view referential_constraints contains all referential (foreign key) constraints in the current database that belong to a table owned by a currently enabled role.

#### Table 33-21. referential_constraints Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>constraint_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the constraint (always the current database)</td>
</tr>
<tr>
<td>constraint_schema</td>
<td>sql_identifier</td>
<td>Name of the schema containing the constraint</td>
</tr>
<tr>
<td>constraint_name</td>
<td>sql_identifier</td>
<td>Name of the constraint</td>
</tr>
<tr>
<td>unique_constraint_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the unique or primary key constraint that the foreign key constraint references (always the current database)</td>
</tr>
<tr>
<td>unique_constraint_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the unique or primary key constraint that the foreign key constraint references</td>
</tr>
<tr>
<td>unique_constraint_name</td>
<td>sql_identifier</td>
<td>Name of the unique or primary key constraint that the foreign key constraint references</td>
</tr>
<tr>
<td>match_option</td>
<td>character_data</td>
<td>Match option of the foreign key constraint: FULL, PARTIAL, or NONE.</td>
</tr>
<tr>
<td>update_rule</td>
<td>character_data</td>
<td>Update rule of the foreign key constraint: CASCADE, SET NULL, SET DEFAULT, RESTRICT, or NO ACTION.</td>
</tr>
</tbody>
</table>
### 33.24. role_column_grants

The view `role_column_grants` identifies all privileges granted on columns where the grantor or grantee is a currently enabled role. Further information can be found under `column_privileges`.

**Table 33-22. role_column_grants Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantor</td>
<td>sql_identifier</td>
<td>Name of the role that granted the privilege</td>
</tr>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>Name of the role that the privilege was granted to</td>
</tr>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table that contains the column (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table that contains the column</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table that contains the column</td>
</tr>
<tr>
<td>column_name</td>
<td>sql_identifier</td>
<td>Name of the column</td>
</tr>
<tr>
<td>privilege_type</td>
<td>character_data</td>
<td>Type of the privilege: SELECT, INSERT, UPDATE, or REFERENCES</td>
</tr>
<tr>
<td>is_grantable</td>
<td>character_data</td>
<td>YES if the privilege is grantable, NO if not</td>
</tr>
</tbody>
</table>

### 33.25. role_routine_grants

The view `role_routine_grants` identifies all privileges granted on functions where the grantor or grantee is a currently enabled role. Further information can be found under `routine_privileges`.

**Table 33-23. role_routine_grants Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantor</td>
<td>sql_identifier</td>
<td>Name of the role that granted the privilege</td>
</tr>
</tbody>
</table>
Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>Name of the role that the privilege was granted to</td>
</tr>
<tr>
<td>specific_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the function (always the current database)</td>
</tr>
<tr>
<td>specific_schema</td>
<td>sql_identifier</td>
<td>Name of the schema containing the function</td>
</tr>
<tr>
<td>specific_name</td>
<td>sql_identifier</td>
<td>The &quot;specific name&quot; of the function. See Section 33.29 for more information.</td>
</tr>
<tr>
<td>routine_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the function (always the current database)</td>
</tr>
<tr>
<td>routine_schema</td>
<td>sql_identifier</td>
<td>Name of the schema containing the function</td>
</tr>
<tr>
<td>routine_name</td>
<td>sql_identifier</td>
<td>Name of the function (might be duplicated in case of overloading)</td>
</tr>
<tr>
<td>privilege_type</td>
<td>character_data</td>
<td>Always EXECUTE (the only privilege type for functions)</td>
</tr>
<tr>
<td>is_grantable</td>
<td>character_data</td>
<td>YES if the privilege is grantable, NO if not</td>
</tr>
</tbody>
</table>

33.26. role_table_grants

The view role_table_grants identifies all privileges granted on tables or views where the grantor or grantee is a currently enabled role. Further information can be found under table_privileges.

Table 33-24. role_table_grants Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantor</td>
<td>sql_identifier</td>
<td>Name of the role that granted the privilege</td>
</tr>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>Name of the role that the privilege was granted to</td>
</tr>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table</td>
</tr>
<tr>
<td>privilege_type</td>
<td>character_data</td>
<td>Type of the privilege: SELECT, DELETE, INSERT, UPDATE, REFERENCES, or TRIGGER</td>
</tr>
</tbody>
</table>
### 33.27. role_usage_grants

The view `role_usage_grants` is meant to identify `USAGE` privileges granted on various kinds of objects to a currently enabled role or by a currently enabled role. In PostgreSQL, this currently only applies to domains, and since domains do not have real privileges in PostgreSQL, this view is empty. Further information can be found under `usage_privileges`. In the future, this view might contain more useful information.

**Table 33-25. role_usage_grants Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantor</td>
<td>sql_identifier</td>
<td>In the future, the name of the role that granted the privilege</td>
</tr>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>In the future, the name of the role that the privilege was granted to</td>
</tr>
<tr>
<td>object_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the object (always the current database)</td>
</tr>
<tr>
<td>object_schema</td>
<td>sql_identifier</td>
<td>Name of the schema containing the object</td>
</tr>
<tr>
<td>object_name</td>
<td>sql_identifier</td>
<td>Name of the object</td>
</tr>
<tr>
<td>object_type</td>
<td>character_data</td>
<td>In the future, the type of the object</td>
</tr>
<tr>
<td>privilege_type</td>
<td>character_data</td>
<td>Always <code>USAGE</code></td>
</tr>
<tr>
<td>is_grantable</td>
<td>character_data</td>
<td>YES if the privilege is grantable, NO if not</td>
</tr>
</tbody>
</table>

### 33.28. routine_privileges

The view `routine_privileges` identifies all privileges granted to a currently enabled role or by a currently enabled role. There is one row for each combination of function, grantor, and grantee.

**Table 33-26. routine_privileges Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantor</td>
<td>sql_identifier</td>
<td>Name of the role that granted the privilege</td>
</tr>
</tbody>
</table>
### 33.29. routines

The view `routines` contains all functions in the current database. Only those functions are shown that the current user has access to (by way of being the owner or having some privilege).

#### Table 33-27. routines Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>specific_catalog</td>
<td><code>sql_identifier</code></td>
<td>Name of the database containing the function (always the current database)</td>
</tr>
<tr>
<td>specific_schema</td>
<td><code>sql_identifier</code></td>
<td>Name of the schema containing the function</td>
</tr>
<tr>
<td>specific_name</td>
<td><code>sql_identifier</code></td>
<td>The &quot;specific name&quot; of the function. See Section 33.29 for more information.</td>
</tr>
<tr>
<td>routine_catalog</td>
<td><code>sql_identifier</code></td>
<td>Name of the database containing the function (always the current database)</td>
</tr>
<tr>
<td>routine_schema</td>
<td><code>sql_identifier</code></td>
<td>Name of the schema containing the function</td>
</tr>
<tr>
<td>routine_name</td>
<td><code>sql_identifier</code></td>
<td>Name of the function (might be duplicated in case of overloading)</td>
</tr>
<tr>
<td>privilege_type</td>
<td><code>character_data</code></td>
<td>Always <code>EXECUTE</code> (the only privilege type for functions)</td>
</tr>
<tr>
<td>is_grantable</td>
<td><code>character_data</code></td>
<td>YES if the privilege is grantable, NO if not</td>
</tr>
</tbody>
</table>

<tr>
<td>maximum_cardinality</td>
<td>cardinal_number</td>
<td>Always null, because arrays always have unlimited maximum cardinality in PostgreSQL.</td>
</tr>
<tr>
<td>dtd_identifier</td>
<td>sql_identifier</td>
<td>An identifier of the data type descriptor of the return data type of this function, unique among the data type descriptors pertaining to the function. This is mainly useful for joining with other instances of such identifiers. (The specific format of the identifier is not defined and not guaranteed to remain the same in future versions.)</td>
</tr>
<tr>
<td>routine_body</td>
<td>character_data</td>
<td>If the function is an SQL function, then SQL, else EXTERNAL.</td>
</tr>
<tr>
<td>routine_definition</td>
<td>character_data</td>
<td>The source text of the function (null if the function is not owned by a currently enabled role). (According to the SQL standard, this column is only applicable if routine_body is SQL, but in PostgreSQL it will contain whatever source text was specified when the function was created.)</td>
</tr>
<tr>
<td>external_name</td>
<td>character_data</td>
<td>If this function is a C function, then the external name (link symbol) of the function; else null. (This works out to be the same value that is shown in routine_definition.)</td>
</tr>
<tr>
<td>external_language</td>
<td>character_data</td>
<td>The language the function is written in.</td>
</tr>
<tr>
<td>parameter_style</td>
<td>character_data</td>
<td>Always GENERAL (The SQL standard defines other parameter styles, which are not available in PostgreSQL.)</td>
</tr>
<tr>
<td>is_deterministic</td>
<td>character_data</td>
<td>If the function is declared immutable (called deterministic in the SQL standard), then YES, else NO. (You cannot query the other volatility levels available in PostgreSQL through the information schema.)</td>
</tr>
</tbody>
</table>
### Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>sql_data_access</td>
<td>character_data</td>
<td>Always <strong>MODIFIES</strong>, meaning that the function possibly modifies SQL data. This information is not useful for PostgreSQL.</td>
</tr>
<tr>
<td>is_null_call</td>
<td>character_data</td>
<td>If the function automatically returns null if any of its arguments are null, then <strong>YES</strong>, else <strong>NO</strong>.</td>
</tr>
<tr>
<td>sql_path</td>
<td>character_data</td>
<td>Applies to a feature not available in PostgreSQL.</td>
</tr>
<tr>
<td>schema_level_routine</td>
<td>character_data</td>
<td>Always <strong>YES</strong> (The opposite would be a method of a user-defined type, which is a feature not available in PostgreSQL.)</td>
</tr>
<tr>
<td>max_dynamic_result_sets</td>
<td>cardinal_number</td>

</table>
33.30. schemata

The view `schemata` contains all schemas in the current database that are owned by a currently enabled role.

Table 33-28. schemata Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>catalog_name</td>
<td>sql_identifier</td>
<td>Name of the database that the schema is contained in (always the current database)</td>
</tr>
<tr>
<td>schema_name</td>
<td>sql_identifier</td>
<td>Name of the schema</td>
</tr>
<tr>
<td>schema_owner</td>
<td>sql_identifier</td>
<td>Name of the owner of the schema</td>
</tr>
<tr>
<td>default_character_set_catalog</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>default_character_set_schema</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>default_character_set_name</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>sql_path</td>
<td>character_data</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
</tbody>
</table>

33.31. sequences

The view `sequences` contains all sequences defined in the current database. Only those sequences are shown that the current user has access to (by way of being the owner or having some privilege).

Table 33-29. sequences Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>sequence_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the sequence (always the current database)</td>
</tr>
<tr>
<td>sequence_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the sequence</td>
</tr>
<tr>
<td>sequence_name</td>
<td>sql_identifier</td>
<td>Name of the sequence</td>
</tr>
<tr>
<td>data_type</td>
<td>character_data</td>
<td>The data type of the sequence. In PostgreSQL, this is currently always bigint.</td>
</tr>
</tbody>
</table>
Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>numeric_precision</td>
<td>cardinal_number</td>
<td>This column contains the (declared or implicit) precision of the sequence data type (see above). The precision indicates the number of significant digits. It can be expressed in decimal (base 10) or binary (base 2) terms, as specified in the column numeric_precision_radix.</td>
</tr>
<tr>
<td>numeric_precision_radix</td>
<td>cardinal_number</td>
<td>This column indicates in which base the values in the columns numeric_precision and numeric_scale are expressed. The value is either 2 or 10.</td>
</tr>
<tr>
<td>numeric_scale</td>
<td>cardinal_number</td>
<td>This column contains the (declared or implicit) scale of the sequence data type (see above). The scale indicates the number of significant digits to the right of the decimal point. It can be expressed in decimal (base 10) or binary (base 2) terms, as specified in the column numeric_precision_radix.</td>
</tr>
<tr>
<td>maximum_value</td>
<td>cardinal_number</td>
<td>Not yet implemented</td>
</tr>
<tr>
<td>minimum_value</td>
<td>cardinal_number</td>
<td>Not yet implemented</td>
</tr>
<tr>
<td>increment</td>
<td>cardinal_number</td>
<td>Not yet implemented</td>
</tr>
<tr>
<td>cycle_option</td>
<td>character_data</td>
<td>Not yet implemented</td>
</tr>
</tbody>
</table>

33.32. sql_features

The table sql_features contains information about which formal features defined in the SQL standard are supported by PostgreSQL. This is the same information that is presented in Appendix D. There you can also find some additional background information.

Table 33-30. sql_features Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>feature_id</td>
<td>character_data</td>
<td>Identifier string of the feature</td>
</tr>
<tr>
<td>feature_name</td>
<td>character_data</td>
<td>Descriptive name of the feature</td>
</tr>
</tbody>
</table>
33.33. sql_implementation_info

The table `sql_implementation_info` contains information about various aspects that are left implementation-defined by the SQL standard. This information is primarily intended for use in the context of the ODBC interface; users of other interfaces will probably find this information to be of little use. For this reason, the individual implementation information items are not described here; you will find them in the description of the ODBC interface.

Table 33-31. sql_implementation_info Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>implementation_info_id</td>
<td>character_data</td>
<td>Identifier string of the implementation information item</td>
</tr>
<tr>
<td>implementation_info_name</td>
<td>character_data</td>
<td>Descriptive name of the implementation information item</td>
</tr>
<tr>
<td>integer_value</td>
<td>cardinal_number</td>
<td>Value of the implementation information item, or null if the value is</td>
</tr>
<tr>
<td></td>
<td></td>
<td>contained in the column <code>character_value</code></td>
</tr>
<tr>
<td>character_value</td>
<td>character_data</td>
<td>Value of the implementation information item, or null if the value is</td>
</tr>
<tr>
<td></td>
<td></td>
<td>contained in the column <code>integer_value</code></td>
</tr>
<tr>
<td>comments</td>
<td>character_data</td>
<td>Possibly a comment pertaining to the implementation information item</td>
</tr>
</tbody>
</table>
33.34. sql_languages

The table sql_languages contains one row for each SQL language binding that is supported by PostgreSQL. PostgreSQL supports direct SQL and embedded SQL in C; that is all you will learn from this table.

Table 33-32. sql_languages Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>sql_language_source</td>
<td>character_data</td>
<td>The name of the source of the language definition; always ISO 9075, that is, the SQL standard</td>
</tr>
<tr>
<td>sql_language_year</td>
<td>character_data</td>
<td>The year the standard referenced in sql_language_source was approved; currently 2003</td>
</tr>
<tr>
<td>sql_language_conformance</td>
<td>character_data</td>
<td>The standard conformance level for the language binding. For ISO 9075:2003 this is always CORE.</td>
</tr>
<tr>
<td>sql_language_integrity</td>
<td>character_data</td>
<td>Always null (This value is relevant to an earlier version of the SQL standard.)</td>
</tr>
<tr>
<td>sql_language_implementation</td>
<td>character_data</td>
<td>Always null</td>
</tr>
<tr>
<td>sql_language_binding_style</td>
<td>character_data</td>
<td>The language binding style, either DIRECT or EMBEDDED</td>
</tr>
<tr>
<td>sql_language_programming</td>
<td>character_data</td>
<td>The programming language, if the binding style is EMBEDDED, else null. PostgreSQL only supports the language C.</td>
</tr>
</tbody>
</table>

33.35. sql_packages

The table sql_packages contains information about which feature packages defined in the SQL standard are supported by PostgreSQL. Refer to Appendix D for background information on feature packages.

Table 33-33. sql_packages Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>feature_id</td>
<td>character_data</td>
<td>Identifier string of the package</td>
</tr>
<tr>
<td>feature_name</td>
<td>character_data</td>
<td>Descriptive name of the package</td>
</tr>
<tr>
<td>is_supported</td>
<td>character_data</td>
<td>YES if the package is fully supported by the current version of PostgreSQL, NO if not</td>
</tr>
</tbody>
</table>
Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>is_verified_by</td>
<td>character_data</td>
<td>Always null, since the PostgreSQL development group does not perform formal testing of feature conformance</td>
</tr>
<tr>
<td>comments</td>
<td>character_data</td>
<td>Possibly a comment about the supported status of the package</td>
</tr>
</tbody>
</table>

### 33.36. sql_parts

The table `sql_parts` contains information about which of the several parts of the SQL standard are supported by PostgreSQL.

**Table 33-34. sql_parts Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>feature_id</td>
<td>character_data</td>
<td>An identifier string containing the number of the part</td>
</tr>
<tr>
<td>feature_name</td>
<td>character_data</td>
<td>Descriptive name of the part</td>
</tr>
<tr>
<td>is_supported</td>
<td>character_data</td>
<td>YES if the part is fully supported by the current version of PostgreSQL, NO if not</td>
</tr>
<tr>
<td>is_verified_by</td>
<td>character_data</td>
<td>Always null, since the PostgreSQL development group does not perform formal testing of feature conformance</td>
</tr>
<tr>
<td>comments</td>
<td>character_data</td>
<td>Possibly a comment about the supported status of the part</td>
</tr>
</tbody>
</table>

### 33.37. sql_sizing

The table `sql_sizing` contains information about various size limits and maximum values in PostgreSQL. This information is primarily intended for use in the context of the ODBC interface; users of other interfaces will probably find this information to be of little use. For this reason, the individual sizing items are not described here; you will find them in the description of the ODBC interface.

**Table 33-35. sql_sizing Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>sizing_id</td>
<td>cardinal_number</td>
<td>Identifier of the sizing item</td>
</tr>
<tr>
<td>sizing_name</td>
<td>character_data</td>
<td>Descriptive name of the sizing item</td>
</tr>
</tbody>
</table>
Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>supported_value</td>
<td>cardinal_number</td>
<td>Value of the sizing item, or 0 if the size is unlimited or cannot be determined, or null if the features for which the sizing item is applicable are not supported</td>
</tr>
<tr>
<td>comments</td>
<td>character_data</td>
<td>Possibly a comment pertaining to the sizing item</td>
</tr>
</tbody>
</table>

### 33.38. sql_sizing_profiles

The table `sql_sizing_profiles` contains information about the `sql_sizing` values that are required by various profiles of the SQL standard. PostgreSQL does not track any SQL profiles, so this table is empty.

**Table 33-36. sql_sizing_profiles Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>sizing_id</td>
<td>cardinal_number</td>
<td>Identifier of the sizing item</td>
</tr>
<tr>
<td>sizing_name</td>
<td>character_data</td>
<td>Descriptive name of the sizing item</td>
</tr>
<tr>
<td>profile_id</td>
<td>character_data</td>
<td>Identifier string of a profile</td>
</tr>
<tr>
<td>required_value</td>
<td>cardinal_number</td>
<td>The value required by the SQL profile for the sizing item, or 0 if the profile places no limit on the sizing item, or null if the profile does not require any of the features for which the sizing item is applicable</td>
</tr>
<tr>
<td>comments</td>
<td>character_data</td>
<td>Possibly a comment pertaining to the sizing item within the profile</td>
</tr>
</tbody>
</table>

### 33.39. table_constraints

The view `table_constraints` contains all constraints belonging to tables that the current user owns or has some privilege on.

**Table 33-37. table_constraints Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>constraint_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the constraint (always the current database)</td>
</tr>
</tbody>
</table>
### Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>constraint_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the constraint</td>
</tr>
<tr>
<td>constraint_name</td>
<td>sql_identifier</td>
<td>Name of the constraint</td>
</tr>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table</td>
</tr>
<tr>
<td>constraint_type</td>
<td>character_data</td>
<td>Type of the constraint: CHECK, FOREIGN KEY, PRIMARY KEY, or UNIQUE</td>
</tr>
<tr>
<td>is_deferrable</td>
<td>character_data</td>
<td>YES if the constraint is deferrable, NO if not</td>
</tr>
<tr>
<td>initially_deferred</td>
<td>character_data</td>
<td>YES if the constraint is deferrable and initially deferred, NO if not</td>
</tr>
</tbody>
</table>

### 33.40. table_privileges

The view *table_privileges* identifies all privileges granted on tables or views to a currently enabled role or by a currently enabled role. There is one row for each combination of table, grantor, and grantee.

#### Table 33-38. table_privileges Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantor</td>
<td>sql_identifier</td>
<td>Name of the role that granted the privilege</td>
</tr>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>Name of the role that the privilege was granted to</td>
</tr>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table</td>
</tr>
<tr>
<td>privilege_type</td>
<td>character_data</td>
<td>Type of the privilege: SELECT, DELETE, INSERT, UPDATE, REFERENCES, or TRIGGER</td>
</tr>
<tr>
<td>is_grantable</td>
<td>character_data</td>
<td>YES if the privilege is grantable, NO if not</td>
</tr>
<tr>
<td>with_hierarchy</td>
<td>character_data</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
</tbody>
</table>
### 33.41. tables

The view tables contains all tables and views defined in the current database. Only those tables and views are shown that the current user has access to (by way of being the owner or having some privilege).

**Table 33-39. tables Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table</td>
</tr>
<tr>
<td>table_type</td>
<td>character_data</td>
<td>Type of the table: BASE TABLE for a persistent base table (the normal table type), VIEW for a view, or LOCAL TEMPORARY for a temporary table</td>
</tr>
<tr>
<td>self_referencing_column_name</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>reference_generation</td>
<td>character_data</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>user_defined_type_catalog</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>user_defined_type_schema</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>user_defined_type_name</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>is_insertable_into</td>
<td>character_data</td>
<td>YES if the table is insertable into, NO if not (Base tables are always insertable into, views not necessarily.)</td>
</tr>
<tr>
<td>is_typed</td>
<td>character_data</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>commit_action</td>
<td>character_data</td>
<td>If the table is a temporary table, then PRESERVE, else null. (The SQL standard defines other commit actions for temporary tables, which are not supported by PostgreSQL.)</td>
</tr>
</tbody>
</table>

### 33.42. triggers

The view triggers contains all triggers defined in the current database on tables that the current user owns or has some privilege on.
<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>trigger_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the trigger (always the current database)</td>
</tr>
<tr>
<td>trigger_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the trigger</td>
</tr>
<tr>
<td>trigger_name</td>
<td>sql_identifier</td>
<td>Name of the trigger</td>
</tr>
<tr>
<td>event_manipulation</td>
<td>character_data</td>
<td>Event that fires the trigger (INSERT, UPDATE, or DELETE)</td>
</tr>
<tr>
<td>event_object_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table that the trigger is defined on (always the current database)</td>
</tr>
<tr>
<td>event_object_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table that the trigger is defined on</td>
</tr>
<tr>
<td>event_object_table</td>
<td>sql_identifier</td>
<td>Name of the table that the trigger is defined on</td>
</tr>
<tr>
<td>action_order</td>
<td>cardinal_number</td>
<td>Not yet implemented</td>
</tr>
<tr>
<td>action_condition</td>
<td>character_data</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>action_statement</td>
<td>character_data</td>
<td>Statement that is executed by the trigger (currently always EXECUTE PROCEDURE function(...))</td>
</tr>
<tr>
<td>action_orientation</td>
<td>character_data</td>
<td>Identifies whether the trigger fires once for each processed row or once for each statement (ROW or STATEMENT)</td>
</tr>
<tr>
<td>condition_timing</td>
<td>character_data</td>
<td>Time at which the trigger fires (BEFORE or AFTER)</td>
</tr>
<tr>
<td>condition_reference_old</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>condition_reference_new</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>condition_reference_old</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>condition_reference_new</td>
<td>sql_identifier</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>
<td>created</td>
<td>time_stamp</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
</tbody>
</table>

Triggers in PostgreSQL have two incompatibilities with the SQL standard that affect the representation in the information schema. First, trigger names are local to the table in PostgreSQL, rather than being independent schema objects. Therefore there can be duplicate trigger names defined in one schema, as long as they belong to different tables. (trigger_catalog and...
trigger_schema are really the values pertaining to the table that the trigger is defined on.) Second, triggers can be defined to fire on multiple events in PostgreSQL (e.g., ON INSERT OR UPDATE), whereas the SQL standard only allows one. If a trigger is defined to fire on multiple events, it is represented as multiple rows in the information schema, one for each type of event. As a consequence of these two issues, the primary key of the view triggers is really (trigger_catalog, trigger_schema, trigger_name, event_object_table, event_manipulation) instead of (trigger_catalog, trigger_schema, trigger_name), which is what the SQL standard specifies. Nonetheless, if you define your triggers in a manner that conforms with the SQL standard (trigger names unique in the schema and only one event type per trigger), this will not affect you.

### 33.43. usage_privileges

The view usage_privileges is meant to identify USAGE privileges granted on various kinds of objects to a currently enabled role or by a currently enabled role. In PostgreSQL, this currently only applies to domains, and since domains do not have real privileges in PostgreSQL, this view shows implicit USAGE privileges granted to PUBLIC for all domains. In the future, this view might contain more useful information.

**Table 33-41. usage_privileges Columns**

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>grantor</td>
<td>sql_identifier</td>
<td>Currently set to the name of the owner of the object</td>
</tr>
<tr>
<td>grantee</td>
<td>sql_identifier</td>
<td>Currently always PUBLIC</td>
</tr>
<tr>
<td>object_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the object (always the current database)</td>
</tr>
<tr>
<td>object_schema</td>
<td>sql_identifier</td>
<td>Name of the schema containing the object</td>
</tr>
<tr>
<td>object_name</td>
<td>sql_identifier</td>
<td>Name of the object</td>
</tr>
<tr>
<td>object_type</td>
<td>character_data</td>
<td>Currently always DOMAIN</td>
</tr>
<tr>
<td>privilege_type</td>
<td>character_data</td>
<td>Always USAGE</td>
</tr>
<tr>
<td>is_grantable</td>
<td>character_data</td>
<td>Currently always NO</td>
</tr>
</tbody>
</table>

### 33.44. view_column_usage

The view view_column_usage identifies all columns that are used in the query expression of a view (the SELECT statement that defines the view). A column is only included if the table that contains the column is owned by a currently enabled role.

**Note:** Columns of system tables are not included. This should be fixed sometime.

**Table 33-42. view_column_usage Columns**
### 33.45. \texttt{view\_routine\_usage}

The \texttt{view\_routine\_usage} identifies all routines (functions and procedures) that are used in the query expression of a view (the \texttt{SELECT} statement that defines the view). A routine is only included if that routine is owned by a currently enabled role.

#### Table 33-43. \texttt{view\_routine\_usage} Columns

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the view (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema containing the view</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the view</td>
</tr>
<tr>
<td>specific_catalog</td>
<td>sql_identifier</td>
<td>Name of the database containing the function (always the current database)</td>
</tr>
<tr>
<td>specific_schema</td>
<td>sql_identifier</td>
<td>Name of the schema containing the function</td>
</tr>
<tr>
<td>specific_name</td>
<td>sql_identifier</td>
<td>The “specific name” of the function. See Section 33.29 for more information.</td>
</tr>
</tbody>
</table>
33.46. **view_table_usage**

The view **view_table_usage** identifies all tables that are used in the query expression of a view (the `SELECT` statement that defines the view). A table is only included if that table is owned by a currently enabled role.

**Note:** System tables are not included. This should be fixed sometime.

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>view_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the view (always the current database)</td>
</tr>
<tr>
<td>view_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the view</td>
</tr>
<tr>
<td>view_name</td>
<td>sql_identifier</td>
<td>Name of the view</td>
</tr>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the table that is used by the view (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the table that is used by the view</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the table that is used by the view</td>
</tr>
</tbody>
</table>

33.47. **views**

The view **views** contains all views defined in the current database. Only those views are shown that the current user has access to (by way of being the owner or having some privilege).

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>table_catalog</td>
<td>sql_identifier</td>
<td>Name of the database that contains the view (always the current database)</td>
</tr>
<tr>
<td>table_schema</td>
<td>sql_identifier</td>
<td>Name of the schema that contains the view</td>
</tr>
<tr>
<td>table_name</td>
<td>sql_identifier</td>
<td>Name of the view</td>
</tr>
<tr>
<td>view_definition</td>
<td>character_data</td>
<td>Query expression defining the view (null if the view is not owned by a currently enabled role)</td>
</tr>
</tbody>
</table>
### Chapter 33. The Information Schema

<table>
<thead>
<tr>
<th>Name</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>check_option</td>
<td>character_data</td>
<td>Applies to a feature not available in PostgreSQL</td>
</tr>
<tr>

<td>character_data</td>
<td>YES if the view is updatable (allows UPDATE and DELETE), NO if not</td>
</tr>
<tr>
<td>is_insertable_into</td>
<td>character_data</td>
<td>YES if the view is insertable into (allows INSERT), NO if not</td>
</tr>
</tbody>
</table>
V. Server Programming

This part is about extending the server functionality with user-defined functions, data types, triggers, etc. These are advanced topics which should probably be approached only after all the other user documentation about PostgreSQL has been understood. Later chapters in this part describe the server-side programming languages available in the PostgreSQL distribution as well as general issues concerning server-side programming languages. It is essential to read at least the earlier sections of Chapter 34 (covering functions) before diving into the material about server-side programming languages.
Chapter 34. Extending SQL

In the sections that follow, we will discuss how you can extend the PostgreSQL SQL query language by adding:

- functions (starting in Section 34.3)
- aggregates (starting in Section 34.10)
- data types (starting in Section 34.11)
- operators (starting in Section 34.12)
- operator classes for indexes (starting in Section 34.14)

34.1. How Extensibility Works

PostgreSQL is extensible because its operation is catalog-driven. If you are familiar with standard relational database systems, you know that they store information about databases, tables, columns, etc., in what are commonly known as system catalogs. (Some systems call this the data dictionary.) The catalogs appear to the user as tables like any other, but the DBMS stores its internal bookkeeping in them. One key difference between PostgreSQL and standard relational database systems is that PostgreSQL stores much more information in its catalogs: not only information about tables and columns, but also information about data types, functions, access methods, and so on. These tables can be modified by the user, and since PostgreSQL bases its operation on these tables, this means that PostgreSQL can be extended by users. By comparison, conventional database systems can only be extended by changing hardcoded procedures in the source code or by loading modules specially written by the DBMS vendor.

The PostgreSQL server can moreover incorporate user-written code into itself through dynamic loading. That is, the user can specify an object code file (e.g., a shared library) that implements a new type or function, and PostgreSQL will load it as required. Code written in SQL is even more trivial to add to the server. This ability to modify its operation “on the fly” makes PostgreSQL uniquely suited for rapid prototyping of new applications and storage structures.

34.2. The PostgreSQL Type System

PostgreSQL data types are divided into base types, composite types, domains, and pseudo-types.

34.2.1. Base Types

Base types are those, like int4, that are implemented below the level of the SQL language (typically in a low-level language such as C). They generally correspond to what are often known as abstract data types. PostgreSQL can only operate on such types through functions provided by the user and only understands the behavior of such types to the extent that the user describes them. Base types are further subdivided into scalar and array types. For each scalar type, a corresponding array type is automatically created that can hold variable-size arrays of that scalar type.
34.2.2. Composite Types

Composite types, or row types, are created whenever the user creates a table. It is also possible to use CREATE TYPE to define a “stand-alone” composite type with no associated table. A composite type is simply a list of types with associated field names. A value of a composite type is a row or record of field values. The user can access the component fields from SQL queries. Refer to Section 8.15 for more information on composite types.

34.2.3. Domains

A domain is based on a particular base type and for many purposes is interchangeable with its base type. However, a domain can have constraints that restrict its valid values to a subset of what the underlying base type would allow.

Domains can be created using the SQL command CREATE DOMAIN. Their creation and use is not discussed in this chapter.

34.2.4. Pseudo-Types

There are a few “pseudo-types” for special purposes. Pseudo-types cannot appear as columns of tables or attributes of composite types, but they can be used to declare the argument and result types of functions. This provides a mechanism within the type system to identify special classes of functions. Table 8-20 lists the existing pseudo-types.

34.2.5. Polymorphic Types

Four pseudo-types of special interest are anyelement, anyarray, anynonarray, and anyenum, which are collectively called polymorphic types. Any function declared using these types is said to be a polymorphic function. A polymorphic function can operate on many different data types, with the specific data type(s) being determined by the data types actually passed to it in a particular call.

Polymorphic arguments and results are tied to each other and are resolved to a specific data type when a query calling a polymorphic function is parsed. Each position (either argument or return value) declared as anyelement is allowed to have any specific actual data type, but in any given call they must all be the same actual type. Each position declared as anyarray can have any array data type, but similarly they must all be the same type. If there are positions declared anyelement and others declared anyarray, the actual array type in the anyarray positions must be an array whose elements are the same type appearing in the anyelement positions. anynonarray is treated exactly the same as anyelement, but adds the additional constraint that the actual type must not be an array type. anyenum is treated exactly the same as anyelement, but adds the additional constraint that the actual type must be an enum type.

Thus, when more than one argument position is declared with a polymorphic type, the net effect is that only certain combinations of actual argument types are allowed. For example, a function declared as equal(anyelement, anyelement) will take any two input values, so long as they are of the same data type.

When the return value of a function is declared as a polymorphic type, there must be at least one argument position that is also polymorphic, and the actual data type supplied as the argument determines the actual result type for that call. For example, if there were not already an array subscripting mechanism, one could define a function that implements subscripting as subscript(anyarray, integer) returns anyelement. This declaration constrains the actual first argument to be an
array type, and allows the parser to infer the correct result type from the actual first argument’s type. Another example is that a function declared as \( f(\text{anyarray}) \) returns anyenum will only accept arrays of enum types.

Note that anynonarray and anyenum do not represent separate type variables; they are the same type as anyelement, just with an additional constraint. For example, declaring a function as \( f(\text{anyelement}, \text{anyenum}) \) is equivalent to declaring it as \( f(\text{anyenum}, \text{anyenum}) \): both actual arguments have to be the same enum type.

### 34.3. User-Defined Functions

PostgreSQL provides four kinds of functions:

- query language functions (functions written in SQL) (Section 34.4)
- procedural language functions (functions written in, for example, PL/pgSQL or PL/Tcl) (Section 34.7)
- internal functions (Section 34.8)
- C-language functions (Section 34.9)

Every kind of function can take base types, composite types, or combinations of these as arguments (parameters). In addition, every kind of function can return a base type or a composite type. Functions can also be defined to return sets of base or composite values.

Many kinds of functions can take or return certain pseudo-types (such as polymorphic types), but the available facilities vary. Consult the description of each kind of function for more details.

It’s easiest to define SQL functions, so we’ll start by discussing those. Most of the concepts presented for SQL functions will carry over to the other types of functions.

Throughout this chapter, it can be useful to look at the reference page of the `CREATE FUNCTION` command to understand the examples better. Some examples from this chapter can be found in `funcs.sql` and `funcs.c` in the `src/tutorial` directory in the PostgreSQL source distribution.

### 34.4. Query Language (SQL) Functions

SQL functions execute an arbitrary list of SQL statements, returning the result of the last query in the list. In the simple (non-set) case, the first row of the last query’s result will be returned. (Bear in mind that “the first row” of a multirow result is not well-defined unless you use `ORDER BY`.) If the last query happens to return no rows at all, the null value will be returned.

Alternatively, an SQL function can be declared to return a set, by specifying the function’s return type as `SETOF sometype`. In this case all rows of the last query’s result are returned. Further details appear below.

The body of an SQL function must be a list of SQL statements separated by semicolons. A semicolon after the last statement is optional. Unless the function is declared to return `void`, the last statement must be a `SELECT`. 
Any collection of commands in the SQL language can be packaged together and defined as a function. Besides SELECT queries, the commands can include data modification queries (INSERT, UPDATE, and DELETE), as well as other SQL commands. (The only exception is that you cannot put BEGIN, COMMIT, ROLLBACK, or SAVEPOINT commands into a SQL function.) However, the final command must be a SELECT that returns whatever is specified as the function’s return type. Alternatively, if you want to define a SQL function that performs actions but has no useful value to return, you can define it as returning void. In that case, the function body must not end with a SELECT. For example, this function removes rows with negative salaries from the emp table:

```
CREATE FUNCTION clean_emp() RETURNS void AS 'DELETE FROM emp
   WHERE salary < 0;
' LANGUAGE SQL;

SELECT clean_emp();
```

```
clean_emp
-----------
(1 row)
```

The syntax of the CREATE FUNCTION command requires the function body to be written as a string constant. It is usually most convenient to use dollar quoting (see Section 4.1.2.2) for the string constant. If you choose to use regular single-quoted string constant syntax, you must double single quote marks (‘) and backslashes (\) (assuming escape string syntax) in the body of the function (see Section 4.1.2.1).

Arguments to the SQL function are referenced in the function body using the syntax $n$: $1 refers to the first argument, $2 to the second, and so on. If an argument is of a composite type, then the dot notation, e.g., $1.name, can be used to access attributes of the argument. The arguments can only be used as data values, not as identifiers. Thus for example this is reasonable:

```
INSERT INTO mytable VALUES ($1);
```

but this will not work:

```
INSERT INTO $1 VALUES (42);
```

### 34.4.1. SQL Functions on Base Types

The simplest possible SQL function has no arguments and simply returns a base type, such as integer:

```
CREATE FUNCTION one() RETURNS integer AS $$
   SELECT 1 AS result;
$$ LANGUAGE SQL;
```

```
-- Alternative syntax for string literal:
CREATE FUNCTION one() RETURNS integer AS 'SELECT 1 AS result;
' LANGUAGE SQL;
```

633
SELECT one();

one
-----
  1

Notice that we defined a column alias within the function body for the result of the function (with the name `result`), but this column alias is not visible outside the function. Hence, the result is labeled `one` instead of `result`.

It is almost as easy to define SQL functions that take base types as arguments. In the example below, notice how we refer to the arguments within the function as `$1` and `$2`.

```sql
CREATE FUNCTION add_em(integer, integer) RETURNS integer AS $$
SELECT $1 + $2;
$$ LANGUAGE SQL;
SELECT add_em(1, 2) AS answer;

answer
--------
   3
```

Here is a more useful function, which might be used to debit a bank account:

```sql
CREATE FUNCTION tf1 (integer, numeric) RETURNS integer AS $$
UPDATE bank
    SET balance = balance - $2
    WHERE accountno = $1;
SELECT 1;
$$ LANGUAGE SQL;

A user could execute this function to debit account 17 by $100.00 as follows:

SELECT tf1(17, 100.0);

In practice one would probably like a more useful result from the function than a constant 1, so a more likely definition is:

```sql
CREATE FUNCTION tf1 (integer, numeric) RETURNS numeric AS $$
UPDATE bank
    SET balance = balance - $2
    WHERE accountno = $1;
SELECT balance FROM bank WHERE accountno = $1;
$$ LANGUAGE SQL;
```

which adjusts the balance and returns the new balance.
Chapter 34. Extending SQL

34.4.2. SQL Functions on Composite Types

When writing functions with arguments of composite types, we must not only specify which argument we want (as we did above with $1$ and $2$) but also the desired attribute (field) of that argument. For example, suppose that emp is a table containing employee data, and therefore also the name of the composite type of each row of the table. Here is a function double_salary that computes what someone’s salary would be if it were doubled:

```sql
CREATE TABLE emp (  
    name text,  
    salary numeric,  
    age integer,  
    cubicle point  
) ;

CREATE FUNCTION double_salary(emp) RETURNS numeric AS $$
    SELECT $1.salary * 2 AS salary;
$$ LANGUAGE SQL;

SELECT name, double_salary(emp.*) AS dream  
FROM emp  
WHERE emp.cubicle ~= point '(2,1)';

name | dream
----- | -------
Bill  |  8400
```

Notice the use of the syntax $1.salary to select one field of the argument row value. Also notice how the calling SELECT command uses * to select the entire current row of a table as a composite value. The table row can alternatively be referenced using just the table name, like this:

```sql
SELECT name, double_salary(emp) AS dream  
FROM emp  
WHERE emp.cubicle ~= point '(2,1)';
```

but this usage is deprecated since it’s easy to get confused.

Sometimes it is handy to construct a composite argument value on-the-fly. This can be done with the ROW construct. For example, we could adjust the data being passed to the function:

```sql
SELECT name, double_salary(ROW(name, salary*1.1, age, cubicle)) AS dream  
FROM emp;
```

It is also possible to build a function that returns a composite type. This is an example of a function that returns a single emp row:

```sql
CREATE FUNCTION new_emp() RETURNS emp AS $$
    SELECT text 'None' AS name,  
           1000.0 AS salary,  
           25 AS age,  
           point '(2,2)' AS cubicle;
$$ LANGUAGE SQL;
```

In this example we have specified each of the attributes with a constant value, but any computation could have been substituted for these constants.
Note two important things about defining the function:

- The select list order in the query must be exactly the same as that in which the columns appear in
  the table associated with the composite type. (Naming the columns, as we did above, is irrelevant
  to the system.)
- You must typecast the expressions to match the definition of the composite type, or you will get
  errors like this:

```
ERROR: function declared to return emp returns varchar instead of text at column 1
```

A different way to define the same function is:

```
CREATE FUNCTION new_emp() RETURNS emp AS $$
    SELECT ROW('None', 1000.0, 25, '(2,2)')::emp;
$$ LANGUAGE SQL;
```

Here we wrote a `SELECT` that returns just a single column of the correct composite type. This isn’t
really better in this situation, but it is a handy alternative in some cases — for example, if we need to
compute the result by calling another function that returns the desired composite value.

We could call this function directly in either of two ways:

```
SELECT new_emp();
```

```
new_emp
---------
(None,1000.0,25,"(2,2)")
```

```
SELECT * FROM new_emp();
```

```
name | salary | age | cubicle
------|--------|-----|---------
None  | 1000.0 | 25 | (2,2)
```

The second way is described more fully in Section 34.4.4.

When you use a function that returns a composite type, you might want only one field (attribute) from
its result. You can do that with syntax like this:

```
SELECT (new_emp()).name;
```

```
name
----
None
```

The extra parentheses are needed to keep the parser from getting confused. If you try to do it without
them, you get something like this:

```
SELECT new_emp().name;
```

```
ERROR: syntax error at or near "." at character 17
LINE 1: SELECT new_emp().name;
```

Another option is to use functional notation for extracting an attribute. The simple way to explain this
is that we can use the notations `attribute(table)` and `table.attribute` interchangeably.
SELECT name(new_emp());

name
------
None

-- This is the same as:
-- SELECT emp.name AS youngster FROM emp WHERE emp.age < 30;

SELECT name(emp) AS youngster FROM emp WHERE age(emp) < 30;

youngster
----------
Sam
Andy

Tip: The equivalence between functional notation and attribute notation makes it possible to use functions on composite types to emulate “computed fields”. For example, using the previous definition for double_salary(emp), we can write

SELECT emp.name, emp.double_salary FROM emp;

An application using this wouldn’t need to be directly aware that double_salary isn’t a real column of the table. (You can also emulate computed fields with views.)

Another way to use a function returning a composite type is to pass the result to another function that accepts the correct row type as input:

CREATE FUNCTION getname(emp) RETURNS text AS $$
SELECT $1.name;
$$ LANGUAGE SQL;

SELECT getname(new_emp());
getname
---------
None
(1 row)

Still another way to use a function that returns a composite type is to call it as a table function, as described in Section 34.4.4.

34.4.3. Functions with Output Parameters

An alternative way of describing a function’s results is to define it with output parameters, as in this example:

CREATE FUNCTION add_em (IN x int, IN y int, OUT sum int)
AS 'SELECT $1 + $2'
LANGUAGE SQL;

SELECT add_em(3,7);
This is not essentially different from the version of add_em shown in Section 34.4.1. The real value of output parameters is that they provide a convenient way of defining functions that return several columns. For example,

```sql
CREATE FUNCTION sum_n_product (x int, y int, OUT sum int, OUT product int)
AS 'SELECT $1 + $2, $1 * $2'
LANGUAGE SQL;
```

```sql
SELECT * FROM sum_n_product(11,42);
```

<table>
<thead>
<tr>
<th>sum</th>
<th>product</th>
</tr>
</thead>
<tbody>
<tr>
<td>53</td>
<td>462</td>
</tr>
</tbody>
</table>

What has essentially happened here is that we have created an anonymous composite type for the result of the function. The above example has the same end result as

```sql
CREATE TYPE sum_prod AS (sum int, product int);
CREATE FUNCTION sum_n_product (int, int) RETURNS sum_prod
AS 'SELECT $1 + $2, $1 * $2'
LANGUAGE SQL;
```

but not having to bother with the separate composite type definition is often handy.

Notice that output parameters are not included in the calling argument list when invoking such a function from SQL. This is because PostgreSQL considers only the input parameters to define the function’s calling signature. That means also that only the input parameters matter when referencing the function for purposes such as dropping it. We could drop the above function with either of

```sql
DROP FUNCTION sum_n_product (x int, y int, OUT sum int, OUT product int);
DROP FUNCTION sum_n_product (int, int);
```

Parameters can be marked as **IN** (the default), **OUT**, or **INOUT**. An **INOUT** parameter serves as both an input parameter (part of the calling argument list) and an output parameter (part of the result record type).

### 34.4.4. SQL Functions as Table Sources

All SQL functions can be used in the **FROM** clause of a query, but it is particularly useful for functions returning composite types. If the function is defined to return a base type, the table function produces a one-column table. If the function is defined to return a composite type, the table function produces a column for each attribute of the composite type.

Here is an example:

```sql
CREATE TABLE foo (fooid int, foosubid int, fooname text);
INSERT INTO foo VALUES (1, 1, 'Joe');
INSERT INTO foo VALUES (1, 2, 'Ed');
INSERT INTO foo VALUES (2, 1, 'Mary');
```
### 34.4.5. SQL Functions Returning Sets

When an SQL function is declared as returning `SETOF sometype`, the function’s final `SELECT` query is executed to completion, and each row it outputs is returned as an element of the result set.

This feature is normally used when calling the function in the `FROM` clause. In this case each row returned by the function becomes a row of the table seen by the query. For example, assume that table `foo` has the same contents as above, and we say:

```sql
CREATE FUNCTION getfoo(int) RETURNS SETOF foo AS $$
    SELECT * FROM foo WHERE fooid = $1;
$$ LANGUAGE SQL;
```

```sql
SELECT * FROM getfoo(1) AS t1;
```

Then we would get:

<table>
<thead>
<tr>
<th>fooid</th>
<th>foosubid</th>
<th>fooname</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>Joe</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>Ed</td>
</tr>
</tbody>
</table>

(2 rows)

It is also possible to return multiple rows with the columns defined by output parameters, like this:

```sql
CREATE FUNCTION sum_n_product_with_tab (x int, OUT sum int, OUT product int) RETURNS SETOF record AS $$
    SELECT x + tab.y, x * tab.y FROM tab;
$$ LANGUAGE SQL;
```

Then we would get:

<table>
<thead>
<tr>
<th>fooid</th>
<th>foosubid</th>
<th>fooname</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>Joe</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>Ed</td>
</tr>
</tbody>
</table>

(2 rows)

The key point here is that you must write `RETURNS SETOF record` to indicate that the function returns multiple rows instead of just one. If there is only one output parameter, write that parameter’s type instead of `record`.

Currently, functions returning sets can also be called in the select list of a query. For each row that the query generates by itself, the function returning set is invoked, and an output row is generated for each element of the function’s result set. Note, however, that this capability is deprecated and might...
be removed in future releases. The following is an example function returning a set from the select list:

```
CREATE FUNCTION listchildren(text) RETURNS SETOF text AS $$
SELECT name FROM nodes WHERE parent = $1
$$ LANGUAGE SQL;
```

```
SELECT * FROM nodes;
  name | parent
-------+--------
  Top  |       
  Child1 | Top
  Child2 | Top
  Child3 | Top
  SubChild1 | Child1
  SubChild2 | Child1
(6 rows)
```

```
SELECT listchildren('Top');

  listchildren
  ------------
   Child1
   Child2
   Child3
(3 rows)
```

```
SELECT name, listchildren(name) FROM nodes;

  name | listchildren
  --------+--------------
   Top | Child1
   Top | Child2
   Top | Child3
  Child1 | SubChild1
  Child1 | SubChild2
(5 rows)
```

In the last `SELECT`, notice that no output row appears for `Child2`, `Child3`, etc. This happens because `listchildren` returns an empty set for those arguments, so no result rows are generated.

### 34.4.6. Polymorphic SQL Functions

SQL functions can be declared to accept and return the polymorphic types `anyelement`, `anyarray`, `anynonarray`, and `anyenum`. See Section 34.2.5 for a more detailed explanation of polymorphic functions. Here is a polymorphic function `make_array` that builds up an array from two arbitrary data type elements:

```
CREATE FUNCTION make_array(anyelement, anyelement) RETURNS anyarray AS $$
SELECT ARRAY[$1, $2];
$$ LANGUAGE SQL;
```

```
SELECT make_array(1, 2) AS intarray, make_array('a'::text, 'b') AS textarray;

  intarray | textarray
----------+-----------
     {1,2} |     {a,b}
(1 row)
```
Notice the use of the typecast 'a'::text to specify that the argument is of type text. This is required if the argument is just a string literal, since otherwise it would be treated as type unknown, and array of unknown is not a valid type. Without the typecast, you will get errors like this:

ERROR: could not determine polymorphic type because input has type "unknown"

It is permitted to have polymorphic arguments with a fixed return type, but the converse is not. For example:

```sql
CREATE FUNCTION is_greater(anyelement, anyelement) RETURNS boolean AS $$
    SELECT $1 > $2;
$$ LANGUAGE SQL;
```

```sql
SELECT is_greater(1, 2);
```

```sql
is_greater
------------
  f
(1 row)
```

```sql
CREATE FUNCTION invalid_func() RETURNS anyelement AS $$
    SELECT 1;
$$ LANGUAGE SQL;
```

```sql
ERROR: cannot determine result data type
DETAIL: A function returning a polymorphic type must have at least one polymorphic argument.
```

Polymorphism can be used with functions that have output arguments. For example:

```sql
CREATE FUNCTION dup (f1 anyelement, OUT f2 anyelement, OUT f3 anyarray) AS 'select $1, array[$1,$1]' LANGUAGE sql;
```

```sql
SELECT * FROM dup(22);
```

```sql
  f2 | f3
----+---------
   22 | {22,22}
(1 row)
```

### 34.5. Function Overloading

More than one function can be defined with the same SQL name, so long as the arguments they take are different. In other words, function names can be overloaded. When a query is executed, the server will determine which function to call from the data types and the number of the provided arguments. Overloading can also be used to simulate functions with a variable number of arguments, up to a finite maximum number.

When creating a family of overloaded functions, one should be careful not to create ambiguities. For instance, given the functions:

```sql
CREATE FUNCTION test(int, real) RETURNS ...
```
CREATE FUNCTION test(smallint, double precision) RETURNS ... 

it is not immediately clear which function would be called with some trivial input like \texttt{test(1, 1.5)}. The currently implemented resolution rules are described in Chapter 10, but it is unwise to design a system that subtly relies on this behavior.

A function that takes a single argument of a composite type should generally not have the same name as any attribute (field) of that type. Recall that \texttt{attribute(table)} is considered equivalent to \texttt{table.attribute}. In the case that there is an ambiguity between a function on a composite type and an attribute of the composite type, the attribute will always be used. It is possible to override that choice by schema-qualifying the function name (that is, \texttt{schema.func(table)}) but it's better to avoid the problem by not choosing conflicting names.

When overloading C-language functions, there is an additional constraint: The C name of each function in the family of overloaded functions must be different from the C names of all other functions, either internal or dynamically loaded. If this rule is violated, the behavior is not portable. You might get a run-time linker error, or one of the functions will get called (usually the internal one). The alternative form of the \texttt{AS} clause for the SQL \texttt{CREATE FUNCTION} command decouples the SQL function name from the function name in the C source code. For instance:

\begin{verbatim}
CREATE FUNCTION test(int) RETURNS int
  AS 'filename', 'test_1arg'
  LANGUAGE C;
CREATE FUNCTION test(int, int) RETURNS int
  AS 'filename', 'test_2arg'
  LANGUAGE C;
\end{verbatim}

The names of the C functions here reflect one of many possible conventions.

### 34.6. Function Volatility Categories

Every function has a \textit{volatility} classification, with the possibilities being \texttt{VOLATILE}, \texttt{STABLE}, or \texttt{IMMUTABLE}. \texttt{VOLATILE} is the default if the \texttt{CREATE FUNCTION} command does not specify a category. The volatility category is a promise to the optimizer about the behavior of the function:

- A \texttt{VOLATILE} function can do anything, including modifying the database. It can return different results on successive calls with the same arguments. The optimizer makes no assumptions about the behavior of such functions. A query using a volatile function will re-evaluate the function at every row where its value is needed.

- A \texttt{STABLE} function cannot modify the database and is guaranteed to return the same results given the same arguments for all rows within a single statement. This category allows the optimizer to optimize multiple calls of the function to a single call. In particular, it is safe to use an expression containing such a function in an index scan condition. (Since an index scan will evaluate the comparison value only once, not once at each row, it is not valid to use a \texttt{VOLATILE} function in an index scan condition.)

- An \texttt{IMMUTABLE} function cannot modify the database and is guaranteed to return the same results given the same arguments forever. This category allows the optimizer to pre-evaluate the function when a query calls it with constant arguments. For example, a query like \texttt{SELECT ... WHERE x = 2 + 2} can be simplified on sight to \texttt{SELECT ... WHERE x = 4}, because the function underlying the integer addition operator is marked \texttt{IMMUTABLE}. 

642
For best optimization results, you should label your functions with the strictest volatility category that is valid for them.

Any function with side-effects must be labeled \texttt{VOLATILE}, so that calls to it cannot be optimized away. Even a function with no side-effects needs to be labeled \texttt{VOLATILE} if its value can change within a single query; some examples are \texttt{random()}, \texttt{currval()}, \texttt{timeofday()}.

There is relatively little difference between \texttt{STABLE} and \texttt{IMMUTABLE} categories when considering simple interactive queries that are planned and immediately executed: it doesn’t matter a lot whether a function is executed once during planning or once during query execution startup. But there is a big difference if the plan is saved and reused later. Labeling a function \texttt{IMMUTABLE} when it really isn’t might allow it to be prematurely folded to a constant during planning, resulting in a stale value being re-used during subsequent uses of the plan. This is a hazard when using prepared statements or when using function languages that cache plans (such as PL/pgSQL).

Because of the snapshotting behavior of MVCC (see Chapter 13) a function containing only \texttt{SELECT} commands can safely be marked \texttt{STABLE}, even if it selects from tables that might be undergoing modifications by concurrent queries. PostgreSQL will execute a \texttt{STABLE} function using the snapshot established for the calling query, and so it will see a fixed view of the database throughout that query.

Also note that the \texttt{current_timestamp} family of functions qualify as stable, since their values do not change within a transaction.

The same snapshotting behavior is used for \texttt{SELECT} commands within \texttt{IMMUTABLE} functions. It is generally unwise to select from database tables within an \texttt{IMMUTABLE} function at all, since the immutability will be broken if the table contents ever change. However, PostgreSQL does not enforce that you do not do that.

A common error is to label a function \texttt{IMMUTABLE} when its results depend on a configuration parameter. For example, a function that manipulates timestamps might well have results that depend on the timezone setting. For safety, such functions should be labeled \texttt{STABLE} instead.

\textbf{Note:} Before PostgreSQL release 8.0, the requirement that \texttt{STABLE} and \texttt{IMMUTABLE} functions cannot modify the database was not enforced by the system. Release 8.0 enforces it by requiring SQL functions and procedural language functions of these categories to contain no SQL commands other than \texttt{SELECT}. (This is not a completely bulletproof test, since such functions could still call \texttt{VOLATILE} functions that modify the database. If you do that, you will find that the \texttt{STABLE} or \texttt{IMMUTABLE} function does not notice the database changes applied by the called function.)

### 34.7. Procedural Language Functions

PostgreSQL allows user-defined functions to be written in other languages besides SQL and C. These other languages are generically called \textit{procedural languages} (PLs). Procedural languages aren’t built into the PostgreSQL server; they are offered by loadable modules. See Chapter 37 and following chapters for more information.

### 34.8. Internal Functions

Internal functions are functions written in C that have been statically linked into the PostgreSQL server. The “body” of the function definition specifies the C-language name of the function, which
need not be the same as the name being declared for SQL use. (For reasons of backwards compatibility, an empty body is accepted as meaning that the C-language function name is the same as the SQL name.)

Normally, all internal functions present in the server are declared during the initialization of the database cluster (initdb), but a user could use CREATE FUNCTION to create additional alias names for an internal function. Internal functions are declared in CREATE FUNCTION with language name internal. For instance, to create an alias for the sqrt function:

```
CREATE FUNCTION square_root(double precision) RETURNS double precision
  AS 'dsqrt'
  LANGUAGE internal
  STRICT;
```

(Most internal functions expect to be declared “strict”.)

Note: Not all “predefined” functions are “internal” in the above sense. Some predefined functions are written in SQL.

### 34.9. C-Language Functions

User-defined functions can be written in C (or a language that can be made compatible with C, such as C++). Such functions are compiled into dynamically loadable objects (also called shared libraries) and are loaded by the server on demand. The dynamic loading feature is what distinguishes “C language” functions from “internal” functions — the actual coding conventions are essentially the same for both. (Hence, the standard internal function library is a rich source of coding examples for user-defined C functions.)

Two different calling conventions are currently used for C functions. The newer “version 1” calling convention is indicated by writing a `PG_FUNCTION_INFO_V1()` macro call for the function, as illustrated below. Lack of such a macro indicates an old-style (“version 0”) function. The language name specified in CREATE FUNCTION is C in either case. Old-style functions are now deprecated because of portability problems and lack of functionality, but they are still supported for compatibility reasons.

#### 34.9.1. Dynamic Loading

The first time a user-defined function in a particular loadable object file is called in a session, the dynamic loader loads that object file into memory so that the function can be called. The CREATE FUNCTION for a user-defined C function must therefore specify two pieces of information for the function: the name of the loadable object file, and the C name (link symbol) of the specific function to call within that object file. If the C name is not explicitly specified then it is assumed to be the same as the SQL function name.

The following algorithm is used to locate the shared object file based on the name given in the CREATE FUNCTION command:

1. If the name is an absolute path, the given file is loaded.
2. If the name starts with the string `$libdir`, that part is replaced by the PostgreSQL package library directory name, which is determined at build time.
3. If the name does not contain a directory part, the file is searched for in the path specified by the configuration variable dynamic_library_path.

4. Otherwise (the file was not found in the path, or it contains a non-absolute directory part), the dynamic loader will try to take the name as given, which will most likely fail. (It is unreliable to depend on the current working directory.)

If this sequence does not work, the platform-specific shared library file name extension (often .so) is appended to the given name and this sequence is tried again. If that fails as well, the load will fail.

It is recommended to locate shared libraries either relative to $libdir or through the dynamic library path. This simplifies version upgrades if the new installation is at a different location. The actual directory that $libdir stands for can be found out with the command `pg_config --pkglibdir`.

The user ID the PostgreSQL server runs as must be able to traverse the path to the file you intend to load. Making the file or a higher-level directory not readable and/or not executable by the postgres user is a common mistake.

In any case, the file name that is given in the `CREATE FUNCTION` command is recorded literally in the system catalogs, so if the file needs to be loaded again the same procedure is applied.

**Note:** PostgreSQL will not compile a C function automatically. The object file must be compiled before it is referenced in a `CREATE FUNCTION` command. See Section 34.9.6 for additional information.

To ensure that a dynamically loaded object file is not loaded into an incompatible server, PostgreSQL checks that the file contains a “magic block” with the appropriate contents. This allows the server to detect obvious incompatibilities, such as code compiled for a different major version of PostgreSQL.

A magic block is required as of PostgreSQL 8.2. To include a magic block, write this in one (and only one) of the module source files, after having included the header `fmgr.h`:

```c
#ifdef PG_MODULE_MAGIC
PG_MODULE_MAGIC;
#endif
```

The `#ifdef` test can be omitted if the code doesn’t need to compile against pre-8.2 PostgreSQL releases.

After it is used for the first time, a dynamically loaded object file is retained in memory. Future calls in the same session to the function(s) in that file will only incur the small overhead of a symbol table lookup. If you need to force a reload of an object file, for example after recompiling it, begin a fresh session.

Optionally, a dynamically loaded file can contain initialization and finalization functions. If the file includes a function named `_PG_init`, that function will be called immediately after loading the file. The function receives no parameters and should return void. If the file includes a function named `_PG_fini`, that function will be called immediately before unloading the file. Likewise, the function receives no parameters and should return void. Note that `_PG_fini` will only be called during an unload of the file, not during process termination. (Presently, unloads are disabled and will never occur, but this may change in the future.)

### 34.9.2. Base Types in C-Language Functions

To know how to write C-language functions, you need to know how PostgreSQL internally represents base data types and how they can be passed to and from functions. Internally, PostgreSQL regards a
base type as a “blob of memory”. The user-defined functions that you define over a type in turn define the way that PostgreSQL can operate on it. That is, PostgreSQL will only store and retrieve the data from disk and use your user-defined functions to input, process, and output the data.

Base types can have one of three internal formats:

- pass by value, fixed-length
- pass by reference, fixed-length
- pass by reference, variable-length

By-value types can only be 1, 2, or 4 bytes in length (also 8 bytes, if sizeof(Datum) is 8 on your machine). You should be careful to define your types such that they will be the same size (in bytes) on all architectures. For example, the long type is dangerous because it is 4 bytes on some machines and 8 bytes on others, whereas int type is 4 bytes on most Unix machines. A reasonable implementation of the int4 type on Unix machines might be:

```c
/* 4-byte integer, passed by value */
typedef int int4;
```

On the other hand, fixed-length types of any size can be passed by-reference. For example, here is a sample implementation of a PostgreSQL type:

```c
/* 16-byte structure, passed by reference */
typedef struct
{
    double x, y;
} Point;
```

Only pointers to such types can be used when passing them in and out of PostgreSQL functions. To return a value of such a type, allocate the right amount of memory with `palloc`, fill in the allocated memory, and return a pointer to it. (Also, if you just want to return the same value as one of your input arguments that’s of the same data type, you can skip the extra `palloc` and just return the pointer to the input value.)

Finally, all variable-length types must also be passed by reference. All variable-length types must begin with a length field of exactly 4 bytes, and all data to be stored within that type must be located in the memory immediately following that length field. The length field contains the total length of the structure, that is, it includes the size of the length field itself.

**Warning**

Never modify the contents of a pass-by-reference input value. If you do so you are likely to corrupt on-disk data, since the pointer you are given might point directly into a disk buffer. The sole exception to this rule is explained in Section 34.10.

As an example, we can define the type text as follows:

```c
typedef struct {
    int4 length;
    char data[1];
} text;
```
Chapter 34. Extending SQL

Obviously, the data field declared here is not long enough to hold all possible strings. Since it’s impossible to declare a variable-size structure in C, we rely on the knowledge that the C compiler won’t range-check array subscripts. We just allocate the necessary amount of space and then access the array as if it were declared the right length. (This is a common trick, which you can read about in many textbooks about C.)

When manipulating variable-length types, we must be careful to allocate the correct amount of memory and set the length field correctly. For example, if we wanted to store 40 bytes in a text structure, we might use a code fragment like this:

```c
#include "postgres.h"
...
char buffer[40]; /* our source data */
...
text *destination = (text *) palloc(VARHDRSZ + 40);
destination->length = VARHDRSZ + 40;
memcpy(destination->data, buffer, 40);
...
```

`VARHDRSZ` is the same as `sizeof(int4)`, but it’s considered good style to use the macro `VARHDRSZ` to refer to the size of the overhead for a variable-length type.

Table 34-1 specifies which C type corresponds to which SQL type when writing a C-language function that uses a built-in type of PostgreSQL. The “Defined In” column gives the header file that needs to be included to get the type definition. (The actual definition might be in a different file that is included by the listed file. It is recommended that users stick to the defined interface.) Note that you should always include `postgres.h` first in any source file, because it declares a number of things that you will need anyway.

**Table 34-1. Equivalent C Types for Built-In SQL Types**

<table>
<thead>
<tr>

</tbody>
</table>

Now that we’ve gone over all of the possible structures for base types, we can show some examples of real functions.

### 34.9.3. Version 0 Calling Conventions

We present the “old style” calling convention first — although this approach is now deprecated, it’s easier to get a handle on initially. In the version-0 method, the arguments and result of the C function are just declared in normal C style, but being careful to use the C representation of each SQL data type as shown above.

Here are some examples:

```c
#include "postgres.h"
#include <string.h>

/* by value */

int
add_one(int arg)
{
    return arg + 1;
}

/* by reference, fixed length */

float8 *
add_one_float8(float8 *arg)
{
    float8  *result = (float8 *) palloc(sizeof(float8));
    *result = *arg + 1.0;
    return result;
}
```
Point *
makepoint(Point *pointx, Point *pointy)
{
    Point *new_point = (Point *) palloc(sizeof(Point));
    new_point->x = pointx->x;
    new_point->y = pointy->y;
    return new_point;
}

/* by reference, variable length */
text *
copytext(text *t)
{
    /*
     * VARSIZE is the total size of the struct in bytes.
     */
    text *new_t = (text *) palloc(VARSIZE(t));
    SET_VARSIZE(new_t, VARSIZE(t));
    /*
     * VARDATA is a pointer to the data region of the struct.
     */
    memcpy((void *) VARDATA(new_t), /* destination */
            (void *) VARDATA(t), /* source */
            VARSIZE(t) - VARHDRSZ); /* how many bytes */
    return new_t;
}

/*
 * add_one(integer) returns integer
*/
text *
concat_text(text *arg1, text *arg2)
{
    int32 new_text_size = VARSIZE(arg1) + VARSIZE(arg2) - VARHDRSZ;
    text *new_text = (text *) palloc(new_text_size);
    SET_VARSIZE(new_text, new_text_size);
    memcpy(VARDATA(new_text), VARDATA(arg1), VARSIZE(arg1) - VARHDRSZ);
    memcpy(VARDATA(new_text) + (VARSIZE(arg1) - VARHDRSZ),
            VARDATA(arg2), VARSIZE(arg2) - VARHDRSZ);
    return new_text;
}

Supposing that the above code has been prepared in file func.c and compiled into a shared object, we could define the functions to PostgreSQL with commands like this:

CREATE FUNCTION add_one(integer) RETURNS integer
    AS 'DIRECTORY/func', 'add_one'
    LANGUAGE C STRICT;

-- note overloading of SQL function name "add_one"
CREATE FUNCTION add_one(double precision) RETURNS double precision
    AS 'DIRECTORY/func', 'add_one_float8'
    LANGUAGE C STRICT;

CREATE FUNCTION makepoint(point, point) RETURNS point
Chapter 34. Extending SQL

AS 'DIRECTORY/funcs', 'makepoint'
LANGUAGE C STRICT;

CREATE FUNCTION copytext(text) RETURNS text
AS 'DIRECTORY/funcs', 'copytext'
LANGUAGE C STRICT;

CREATE FUNCTION concat_text(text, text) RETURNS text
AS 'DIRECTORY/funcs', 'concat_text'
LANGUAGE C STRICT;

Here, DIRECTORY stands for the directory of the shared library file (for instance the PostgreSQL tutorial directory, which contains the code for the examples used in this section). (Better style would be to use just 'funcs' in the AS clause, after having added DIRECTORY to the search path. In any case, we can omit the system-specific extension for a shared library, commonly .so or .sl.)

Notice that we have specified the functions as “strict”, meaning that the system should automatically assume a null result if any input value is null. By doing this, we avoid having to check for null inputs in the function code. Without this, we’d have to check for null values explicitly, by checking for a null pointer for each pass-by-reference argument. (For pass-by-value arguments, we don’t even have a way to check!)

Although this calling convention is simple to use, it is not very portable; on some architectures there are problems with passing data types that are smaller than int this way. Also, there is no simple way to return a null result, nor to cope with null arguments in any way other than making the function strict. The version-1 convention, presented next, overcomes these objections.

34.9.4. Version 1 Calling Conventions

The version-1 calling convention relies on macros to suppress most of the complexity of passing arguments and results. The C declaration of a version-1 function is always:

Datum funcname(PG_FUNCTION_ARGS)

In addition, the macro call:

PG_FUNCTION_INFO_V1(funcname);

must appear in the same source file. (Conventionally, it’s written just before the function itself.) This macro call is not needed for internal-language functions, since PostgreSQL assumes that all internal functions use the version-1 convention. It is, however, required for dynamically-loaded functions.

In a version-1 function, each actual argument is fetched using a PG_GETARG_xxx() macro that corresponds to the argument’s data type, and the result is returned using a PG_RETURN_xxx() macro for the return type. PG_GETARG_xxx() takes as its argument the number of the function argument to fetch, where the count starts at 0. PG_RETURN_xxx() takes as its argument the actual value to return.

Here we show the same functions as above, coded in version-1 style:

#include "postgres.h"
#include <string.h>
#include "fmgr.h"

/* by value */
Chapter 34. Extending SQL

PG_FUNCTION_INFO_V1(add_one);

Datum
add_one(PG_FUNCTION_ARGS)
{
    int32 arg = PG_GETARG_INT32(0);
    PG_RETURN_INT32(arg + 1);
}

/* by reference, fixed length */
PG_FUNCTION_INFO_V1(add_one_float8);

Datum
add_one_float8(PG_FUNCTION_ARGS)
{
    /* The macros for FLOAT8 hide its pass-by-reference nature. */
    float8 arg = PG_GETARG_FLOAT8(0);
    PG_RETURN_FLOAT8(arg + 1.0);
}

PG_FUNCTION_INFO_V1(makepoint);

Datum
makepoint(PG_FUNCTION_ARGS)
{
    /* Here, the pass-by-reference nature of Point is not hidden. */
    Point *pointx = PG_GETARG_POINT_P(0);
    Point *pointy = PG_GETARG_POINT_P(1);
    Point *new_point = (Point *) palloc(sizeof(Point));

    new_point->x = pointx->x;
    new_point->y = pointy->y;

    PG_RETURN_POINT_P(new_point);
}

/* by reference, variable length */
PG_FUNCTION_INFO_V1(copytext);

Datum
copytext(PG_FUNCTION_ARGS)
{
    text *t = PG_GETARG_TEXT_P(0);
    /*
     * VARSIZE is the total size of the struct in bytes.
     */
    text *new_t = {text *} palloc(VARSIZE(t));
    SET_VARSIZE(new_t, VARSIZE(t));
    /*
     * VARDATA is a pointer to the data region of the struct.
     */
    memcpy((void *) VARDATA(new_t), /* destination */ (void *) VARDATA(t), /* source */
VARSIZE(t) - VARHDRSZ); /* how many bytes */
PG_RETURN_TEXT_P(new_t);
}

PG_FUNCTION_INFO_V1(concat_text);

Datum
concat_text(PG_FUNCTION_ARGS)
{
  text  *arg1 = PG_GETARG_TEXT_P(0);
  text  *arg2 = PG_GETARG_TEXT_P(1);
  int32 new_text_size = VARSIZE(arg1) + VARSIZE(arg2) - VARHDRSZ;
  text *new_text = (text *) palloc(new_text_size);
  SET_VARSIZE(new_text, new_text_size);
  memcpy(VARDATA(new_text), VARDATA(arg1), VARSIZE(arg1) - VARHDRSZ);
  memcpy(VARDATA(new_text) + (VARSIZE(arg1) - VARHDRSZ),
          VARDATA(arg2), VARSIZE(arg2) - VARHDRSZ);
  PG_RETURN_TEXT_P(new_text);
}

The CREATE FUNCTION commands are the same as for the version-0 equivalents.

At first glance, the version-1 coding conventions might appear to be just pointless obscurantism. They
do, however, offer a number of improvements, because the macros can hide unnecessary detail. An
example is that in coding add_one_float8, we no longer need to be aware that float8 is a pass-
by-reference type. Another example is that the GETARG macros for variable-length types allow for
more efficient fetching of “toasted” (compressed or out-of-line) values.

One big improvement in version-1 functions is better handling of null inputs and results. The macro
PG_ARGISNULL(n) allows a function to test whether each input is null. (Of course, doing this is
only necessary in functions not declared “strict”.) As with the PG_GETARG_xxx() macros, the
input arguments are counted beginning at zero. Note that one should refrain from executing
PG_GETARG_xxx() until one has verified that the argument isn’t null. To return a null result, execute
PG_RETURN_NULL(); this works in both strict and nonstrict functions.

Other options provided in the new-style interface are two variants of the PG_GETARG_xxx() macros.
The first of these, PG_GETARG_xxx_COPY(), guarantees to return a copy of the specified argument
that is safe for writing into. (The normal macros will sometimes return a pointer to a value that is
physically stored in a table, which must not be written to. Using the PG_GETARG_xxx_COPY() macros guarantees a writable result.) The second variant consists of the PG_GETARG_xxx_SLICE() macros which take three arguments. The first is the number of the function argument (as above). The
second and third are the offset and length of the segment to be returned. Offsets are counted from
zero, and a negative length requests that the remainder of the value be returned. These macros provide
more efficient access to parts of large values in the case where they have storage type “external”.
(The storage type of a column can be specified using ALTER TABLE tablename ALTER COLUMN
colname SET STORAGE storagetype. storagetype is one of plain, external, extended, or
main.)

Finally, the version-1 function call conventions make it possible to return set results (Section 34.9.10)
and implement trigger functions (Chapter 35) and procedural-language call handlers (Chapter 48).
Version-1 code is also more portable than version-0, because it does not break restrictions on function
call protocol in the C standard. For more details see src/backend/utils/fmgr/README in the
source distribution.
34.9.5. Writing Code

Before we turn to the more advanced topics, we should discuss some coding rules for PostgreSQL C-language functions. While it might be possible to load functions written in languages other than C into PostgreSQL, this is usually difficult (when it is possible at all) because other languages, such as C++, FORTRAN, or Pascal often do not follow the same calling convention as C. That is, other languages do not pass argument and return values between functions in the same way. For this reason, we will assume that your C-language functions are actually written in C.

The basic rules for writing and building C functions are as follows:

- Use `pg_config --includedir-server` to find out where the PostgreSQL server header files are installed on your system (or the system that your users will be running on).
- Compiling and linking your code so that it can be dynamically loaded into PostgreSQL always requires special flags. See Section 34.9.6 for a detailed explanation of how to do it for your particular operating system.
- Remember to define a “magic block” for your shared library, as described in Section 34.9.1.
- When allocating memory, use the PostgreSQL functions `palloc` and `pfree` instead of the corresponding C library functions `malloc` and `free`. The memory allocated by `palloc` will be freed automatically at the end of each transaction, preventing memory leaks.
- Always zero the bytes of your structures using `memset`. Without this, it’s difficult to support hash indexes or hash joins, as you must pick out only the significant bits of your data structure to compute a hash. Even if you initialize all fields of your structure, there might be alignment padding (holes in the structure) that contain garbage values.
- Most of the internal PostgreSQL types are declared in `postgres.h`, while the function manager interfaces (e.g., `PG_FUNCTION_ARGS`, etc.) are in `fmgr.h`, so you will need to include at least these two files. For portability reasons it’s best to include `postgres.h` first, before any other system or user header files. Including `postgres.h` will also include `elog.h` and `palloc.h` for you.
- Symbol names defined within object files must not conflict with each other or with symbols defined in the PostgreSQL server executable. You will have to rename your functions or variables if you get error messages to this effect.

34.9.6. Compiling and Linking Dynamically-Loaded Functions

Before you are able to use your PostgreSQL extension functions written in C, they must be compiled and linked in a special way to produce a file that can be dynamically loaded by the server. To be precise, a shared library needs to be created.

For information beyond what is contained in this section you should read the documentation of your operating system, in particular the manual pages for the C compiler, `cc`, and the link editor, `ld`. In addition, the PostgreSQL source code contains several working examples in the `contrib` directory. If you rely on these examples you will make your modules dependent on the availability of the PostgreSQL source code, however.

Creating shared libraries is generally analogous to linking executables: first the source files are compiled into object files, then the object files are linked together. The object files need to be created as position-independent code (PIC), which conceptually means that they can be placed at an arbitrary location in memory when they are loaded by the executable. (Object files intended for executables
are usually not compiled that way.) The command to link a shared library contains special flags to
distinguish it from linking an executable (at least in theory — on some systems the practice is much
uglier).

In the following examples we assume that your source code is in a file foo.c and we will create a
shared library foo.so. The intermediate object file will be called foo.o unless otherwise noted. A
shared library can contain more than one object file, but we only use one here.

**BSD/OS**

The compiler flag to create PIC is `-fpic`. The linker flag to create shared libraries is `-shared`.

```
gcc -fpic -c foo.c
ld -shared -o foo.so foo.o
```

This is applicable as of version 4.0 of BSD/OS.

**FreeBSD**

The compiler flag to create PIC is `-fpic`. To create shared libraries the compiler flag is `-shared`.

```
gcc -fpic -c foo.c
gcc -shared -o foo.so foo.o
```

This is applicable as of version 3.0 of FreeBSD.

**HP-UX**

The compiler flag of the system compiler to create PIC is `+z`. When using GCC it’s `-fpic`. The
linker flag for shared libraries is `-b`. So:

```
cc +z -c foo.c
```

or:

```
gcc -fpic -c foo.c
```

and then:

```
ld -b -o foo.sl foo.o
```

HP-UX uses the extension `.sl` for shared libraries, unlike most other systems.

**IRIX**

PIC is the default, no special compiler options are necessary. The linker option to produce shared
libraries is `-shared`.

```
cc -c foo.c
ld -shared -o foo.so foo.o
```

**Linux**

The compiler flag to create PIC is `-fpic`. On some platforms in some situations `-fPIC` must be
used if `-fpic` does not work. Refer to the GCC manual for more information. The compiler flag
to create a shared library is `-shared`. A complete example looks like this:

```
cc -fpic -c foo.c
c -shared -o foo.so foo.o
```

**MacOS X**

Here is an example. It assumes the developer tools are installed.

```
cc -c foo.c
c -bundle -flat_namespace -undefined suppress -o foo.so foo.o
```
Chapter 34. Extending SQL

NetBSD

The compiler flag to create PIC is `-fpic`. For ELF systems, the compiler with the flag `-shared` is used to link shared libraries. On the older non-ELF systems, `ld -Bshareable` is used.

```
gcc -fpic -c foo.c
```

```
gcc -shared -o foo.so foo.o
```

OpenBSD

The compiler flag to create PIC is `-fpic`. `ld -Bshareable` is used to link shared libraries.

```
gcc -fpic -c foo.c
```

```
ld -Bshareable -o foo.so foo.o
```

Solaris

The compiler flag to create PIC is `-KPIC` with the Sun compiler and `-fpic` with GCC. To link shared libraries, the compiler option is `-G` with either compiler or alternatively `-shared` with GCC.

```
cc -KPIC -c foo.c
```

```
cc -G -o foo.so foo.o
```

or

```
gcc -fpic -c foo.c
```

```
gcc -G -o foo.so foo.o
```

Tru64 UNIX

PIC is the default, so the compilation command is the usual one. `ld` with special options is used to do the linking.

```
cc -c foo.c
```

```
ld -shared -expect_unresolved '*' -o foo.so foo.o
```

The same procedure is used with GCC instead of the system compiler; no special options are required.

UnixWare

The compiler flag to create PIC is `-K PIC` with the SCO compiler and `-fpic` with GCC. To link shared libraries, the compiler option is `-G` with the SCO compiler and `-shared` with GCC.

```
cc -K PIC -c foo.c
```

```
cc -G -o foo.so foo.o
```

or

```
gcc -fpic -c foo.c
```

```
gcc -shared -o foo.so foo.o
```

**Tip:** If this is too complicated for you, you should consider using GNU Libtool\(^1\), which hides the platform differences behind a uniform interface.

The resulting shared library file can then be loaded into PostgreSQL. When specifying the file name to the `CREATE FUNCTION` command, one must give it the name of the shared library file, not the intermediate object file. Note that the system’s standard shared-library extension (usually `.so` or `.sl`) can be omitted from the `CREATE FUNCTION` command, and normally should be omitted for best portability.

Refer back to Section 34.9.1 about where the server expects to find the shared library files.

---

\(^1\) [http://www.gnu.org/software/libtool/](http://www.gnu.org/software/libtool/)
34.9.7. Extension Building Infrastructure

If you are thinking about distributing your PostgreSQL extension modules, setting up a portable build system for them can be fairly difficult. Therefore the PostgreSQL installation provides a build infrastructure for extensions, called PGXS, so that simple extension modules can be built simply against an already installed server. Note that this infrastructure is not intended to be a universal build system framework that can be used to build all software interfacing to PostgreSQL; it simply automates common build rules for simple server extension modules. For more complicated packages, you need to write your own build system.

To use the infrastructure for your extension, you must write a simple makefile. In that makefile, you need to set some variables and finally include the global PGXS makefile. Here is an example that builds an extension module named `isbn_issn` consisting of a shared library, an SQL script, and a documentation text file:

```makefile
MODULES = isbn_issn
DATA_built = isbn_issn.sql
DOCS = README.isbn_issn

PG_CONFIG = pg_config
PGXS := $(shell $(PG_CONFIG) --pgxs)
include $(PGXS)
```

The last three lines should always be the same. Earlier in the file, you assign variables or add custom make rules.

The following variables can be set:

- **MODULES**
  - list of shared objects to be built from source file with same stem (do not include suffix in this list)

- **DATA**
  - random files to install into `prefix/share/contrib`

- **DATA_built**
  - random files to install into `prefix/share/contrib`, which need to be built first

- **DOCS**
  - random files to install under `prefix/doc/contrib`

- **SCRIPTS**
  - script files (not binaries) to install into `prefix/bin`

- **SCRIPTS_built**
  - script files (not binaries) to install into `prefix/bin`, which need to be built first

- **REGRESS**
  - list of regression test cases (without suffix), see below
  - or at most one of these two:

- **PROGRAM**
  - a binary program to build (list objects files in `OBJJS`)
MODULE_big

a shared object to build (list object files in OBJJS)

The following can also be set:

EXTRA_CLEAN

extra files to remove in make clean

PG_CPPFLAGS

will be added to CPPFLAGS

PG_LIBS

will be added to PROGRAM link line

SHLIB_LINK

will be added to MODULE_big link line

PG_CONFIG

path to pg_config program for the PostgreSQL installation to build against (typically just pg_config to use the first one in your PATH)

Put this makefile as Makefile in the directory which holds your extension. Then you can do make to compile, and later make install to install your module. By default, the extension is compiled and installed for the PostgreSQL installation that corresponds to the first pg_config program found in your path. You can use a different installation by setting PG_CONFIG to point to its pg_config program, either within the makefile or on the make command line.

Caution
Changing PG_CONFIG only works when building against PostgreSQL 8.3 or later. With older releases it does not work to set it to anything except pg_config; you must alter your PATH to select the installation to build against.

The scripts listed in the REGRESS variable are used for regression testing of your module, just like make installcheck is used for the main PostgreSQL server. For this to work you need to have a subdirectory named sql/ in your extension’s directory, within which you put one file for each group of tests you want to run. The files should have extension .sql, which should not be included in the REGRESS list in the makefile. For each test there should be a file containing the expected result in a subdirectory named expected/, with extension .out. The tests are run by executing make installcheck, and the resulting output will be compared to the expected files. The differences will be written to the file regression.diffs in diff -c format. Note that trying to run a test which is missing the expected file will be reported as “trouble”, so make sure you have all expected files.

Tip: The easiest way of creating the expected files is creating empty files, then carefully inspecting the result files after a test run (to be found in the results/ directory), and copying them to expected/ if they match what you want from the test.
34.9.8. Composite-Type Arguments

Composite types do not have a fixed layout like C structures. Instances of a composite type can contain null fields. In addition, composite types that are part of an inheritance hierarchy can have different fields than other members of the same inheritance hierarchy. Therefore, PostgreSQL provides a function interface for accessing fields of composite types from C.

Suppose we want to write a function to answer the query:

```
SELECT name, c_overpaid(emp, 1500) AS overpaid
FROM emp
WHERE name = 'Bill' OR name = 'Sam';
```

Using call conventions version 0, we can define `c_overpaid` as:

```c
#include "postgres.h"
#include "executor/executor.h" /* for GetAttributeByName() */

bool
c_overpaid(HeapTupleHeader t, /* the current row of emp */
int32 limit)
{
  bool isnull;
  int32 salary;

  salary = DatumGetInt32(GetAttributeByName(t, "salary", &isnull));
  if (isnull)
    return false;
  return salary > limit;
}
```

In version-1 coding, the above would look like this:

```c
#include "postgres.h"
#include "executor/executor.h" /* for GetAttributeByName() */

PG_FUNCTION_INFO_V1(c_overpaid);

Datum
c_overpaid(PG_FUNCTION_ARGS)
{
  HeapTupleHeader t = PG_GETARG_HEAPTUPLEHEADER(0);
  int32 limit = PG_GETARG_INT32(1);
  bool isnull;
  Datum salary;

  salary = GetAttributeByName(t, "salary", &isnull);
  if (isnull)
    PG_RETURN_BOOL(false);
  /* Alternatively, we might prefer to do PG_RETURN_NULL() for null salary. */
  PG_RETURN_BOOL(DatumGetInt32(salary) > limit);
}
```
GetAttributeByName is the PostgreSQL system function that returns attributes out of the specified row. It has three arguments: the argument of type HeapTupleHeader passed into the function, the name of the desired attribute, and a return parameter that tells whether the attribute is null. GetAttributeByName returns a Datum value that you can convert to the proper data type by using the appropriate DatumGetXXX() macro. Note that the return value is meaningless if the null flag is set; always check the null flag before trying to do anything with the result.

There is also GetAttributeByNum, which selects the target attribute by column number instead of name.

The following command declares the function c_overpaid in SQL:

```sql
CREATE FUNCTION c_overpaid(emp, integer) RETURNS boolean
AS 'DIRECTORY/funcs', 'c_overpaid'
LANGUAGE C STRICT;
```

Notice we have used STRICT so that we did not have to check whether the input arguments were NULL.

### 34.9.9. Returning Rows (Composite Types)

To return a row or composite-type value from a C-language function, you can use a special API that provides macros and functions to hide most of the complexity of building composite data types. To use this API, the source file must include:

```c
#include "funcapi.h"
```

There are two ways you can build a composite data value (henceforth a “tuple”): you can build it from an array of Datum values, or from an array of C strings that can be passed to the input conversion functions of the tuple’s column data types. In either case, you first need to obtain or construct a TupleDesc descriptor for the tuple structure. When working with Datums, you pass the TupleDesc to BlessTupleDesc, and then call heap_form_tuple for each row. When working with C strings, you pass the TupleDesc to TupleDescGetAttInMetadata, and then call BuildTupleFromCStrings for each row. In the case of a function returning a set of tuples, the setup steps can all be done once during the first call of the function.

Several helper functions are available for setting up the needed TupleDesc. The recommended way to do this in most functions returning composite values is to call:

```c
TypeFuncClass get_call_result_type(FunctionCallInfo fcinfo,
    Oid *resultTypeId,
    TupleDesc *resultTupleDesc)
```

passing the same fcinfo struct passed to the calling function itself. (This of course requires that you use the version-1 calling conventions.) resultTypeId can be specified as NULL or as the address of a local variable to receive the function’s result type OID. resultTupleDesc should be the address of a local TupleDesc variable. Check that the result is TYPEFUNC_COMPOSITE; if so, resultTupleDesc has been filled with the needed TupleDesc. (If it is not, you can report an error along the lines of “function returning record called in context that cannot accept type record”.)

**Tip:** get_call_result_type can resolve the actual type of a polymorphic function result; so it is useful in functions that return scalar polymorphic results, not only functions that return composites. The resultTypeId output is primarily useful for functions returning polymorphic scalars.
Note: get_call_result_type has a sibling get_expr_result_type, which can be used to resolve the expected output type for a function call represented by an expression tree. This can be used when trying to determine the result type from outside the function itself. There is also get_func_result_type, which can be used when only the function's OID is available. However these functions are not able to deal with functions declared to return record, and get_func_result_type cannot resolve polymorphic types, so you should preferentially use get_call_result_type.

Older, now-deprecated functions for obtaining TupleDescs are:

TupleDesc RelationNameGetTupleDesc(const char *relname)

to get a TupleDesc for the row type of a named relation, and:

TupleDesc TypeGetTupleDesc(Oid typeoid, List *colaliases)

to get a TupleDesc based on a type OID. This can be used to get a TupleDesc for a base or composite type. It will not work for a function that returns record, however, and it cannot resolve polymorphic types.

Once you have a TupleDesc, call:

TupleDesc BlessTupleDesc(TupleDesc tupdesc)

if you plan to work with Datums, or:

AttInMetadata *TupleDescGetAttInMetadata(TupleDesc tupdesc)

if you plan to work with C strings. If you are writing a function returning set, you can save the results of these functions in the FuncCallContext structure — use the tuple_desc or attinmeta field respectively.

When working with Datums, use:

HeapTuple heap_form_tuple(TupleDesc tupdesc, Datum *values, bool *isnull)

to build a HeapTuple given user data in Datum form.

When working with C strings, use:

HeapTuple BuildTupleFromCStrings(AttInMetadata *attinmeta, char **values)

to build a HeapTuple given user data in C string form. values is an array of C strings, one for each attribute of the return row. Each C string should be in the form expected by the input function of the attribute data type. In order to return a null value for one of the attributes, the corresponding pointer in the values array should be set to NULL. This function will need to be called again for each row you return.

Once you have built a tuple to return from your function, it must be converted into a Datum. Use:

HeapTupleGetDatum(HeapTuple tuple)

to convert a HeapTuple into a valid Datum. This Datum can be returned directly if you intend to return just a single row, or it can be used as the current return value in a set-returning function.

An example appears in the next section.
34.9.10. Returning Sets

There is also a special API that provides support for returning sets (multiple rows) from a C-language function. A set-returning function must follow the version-1 calling conventions. Also, source files must include `funcapi.h`, as above.

A set-returning function (SRF) is called once for each item it returns. The SRF must therefore save enough state to remember what it was doing and return the next item on each call. The structure `FuncCallContext` is provided to help control this process. Within a function, `fcinfo->flinfo->fn_extra` is used to hold a pointer to `FuncCallContext` across calls.

typedef struct
{
    /*
     * Number of times we’ve been called before
     * call_cntr is initialized to 0 for you by SRF_FIRSTCALL_INIT(), and
     * incremented for you every time SRF_RETURN_NEXT() is called.
     */
    uint32 call_cntr;

    /*
     * OPTIONAL maximum number of calls
     * max_calls is here for convenience only and setting it is optional.
     * If not set, you must provide alternative means to know when the
     * function is done.
     */
    uint32 max_calls;

    /*
     * OPTIONAL pointer to result slot
     * This is obsolete and only present for backwards compatibility, viz,
     * user-defined SRFs that use the deprecated TupleDescGetSlot().
     */
    TupleTableSlot *slot;

    /*
     * OPTIONAL pointer to miscellaneous user-provided context information
     * user_fctx is for use as a pointer to your own data to retain
     * arbitrary context information between calls of your function.
     */
    void *user_fctx;

    /*
     * OPTIONAL pointer to struct containing attribute type input metadata
     * attinmeta is for use when returning tuples (i.e., composite data types)
     * and is not used when returning base data types. It is only needed
     * if you intend to use BuildTupleFromCStrings() to create the return
     * tuple.
     */
    AttInMetadata *attinmeta;

    /*
     * memory context used for structures that must live for multiple calls
     */
} FuncCallContext;
Chapter 34. Extending SQL

* multi_call_memory_ctx is set by SRF_FIRSTCALL_INIT() for you, and used
  by SRF_RETURN_DONE() for cleanup. It is the most appropriate memory
  context for any memory that is to be reused across multiple calls
  of the SRF.
*/
MemoryContext multi_call_memory_ctx;

/*********************************
* OPTIONAL pointer to struct containing tuple description
* tuple_desc is for use when returning tuples (i.e. composite data types)
* and is only needed if you are going to build the tuples with
* heap_form_tuple() rather than with BuildTupleFromCStrings(). Note that
* the TupleDesc pointer stored here should usually have been run through
* BlessTupleDesc() first.
*/
TupleDesc tuple_desc;
}

An SRF uses several functions and macros that automatically manipulate the FuncCallContext structure (and expect to find it via fn_extra). Use:

SRF_IS_FIRSTCALL()

to determine if your function is being called for the first or a subsequent time. On the first call (only) use:

SRF_FIRSTCALL_INIT()

to initialize the FuncCallContext. On every function call, including the first, use:

SRF_PERCALL_SETUP()

to properly set up for using the FuncCallContext and clearing any previously returned data left over from the previous pass.

If your function has data to return, use:

SRF_RETURN_NEXT(funcctx, result)

to return it to the caller. (result must be of type Datum, either a single value or a tuple prepared as described above.) Finally, when your function is finished returning data, use:

SRF_RETURN_DONE(funcctx)

to clean up and end the SRF.

The memory context that is current when the SRF is called is a transient context that will be cleared between calls. This means that you do not need to call pfree on everything you allocated using palloc; it will go away anyway. However, if you want to allocate any data structures to live across calls, you need to put them somewhere else. The memory context referenced by multi_call_memory_ctx is a suitable location for any data that needs to survive until the SRF is finished running. In most cases, this means that you should switch into multi_call_memory_ctx while doing the first-call setup.

A complete pseudo-code example looks like the following:
Datum
my_set_returning_function(PG_FUNCTION_ARGS)
{
    FuncCallContext *funcctx;
    Datum result;
    MemoryContext oldcontext;
    further declarations as needed

    if (SRF_IS_FIRSTCALL())
    {
        funcctx = SRF_FIRSTCALL_INIT();
        oldcontext = MemoryContextSwitchTo(funcctx->multi_call_memory_ctx);
        /* One-time setup code appears here: */
        user code
        if returning composite
            build TupleDesc, and perhaps AttInMetadata
        endif returning composite
        user code
        MemoryContextSwitchTo(oldcontext);
    }
    /* Each-time setup code appears here: */
    user code
    funcctx = SRF_PERCALL_SETUP();
    user code

    /* this is just one way we might test whether we are done: */
    if (funcctx->call_cntr < funcctx->max_calls)
    {
        /* Here we want to return another item: */
        user code
        obtain result Datum
        SRF_RETURN_NEXT(funcctx, result);
    }
    else
    {
        /* Here we are done returning items and just need to clean up: */
        user code
        SRF_RETURN_DONE(funcctx);
    }
}

A complete example of a simple SRF returning a composite type looks like:

PG_FUNCTION_INFO_V1(retcomposite);

Datum
retcomposite(PG_FUNCTION_ARGS)
{
    FuncCallContext *funcctx;
    int call_cntr;
    int max_calls;
    TupleDesc tupdesc;
    AttInMetadata *attinmeta;

    /* stuff done only on the first call of the function */
if (SRF_IS_FIRSTCALL())
{
    MemoryContext oldcontext;

    /* create a function context for cross-call persistence */
    funcctx = SRF_FIRSTCALL_INIT();

    /* switch to memory context appropriate for multiple function calls */
    oldcontext = MemoryContextSwitchTo(funcctx->multi_call_memory_ctx);

    /* total number of tuples to be returned */
    funcctx->max_calls = PG_GETARG_UINT32(0);

    /* Build a tuple descriptor for our result type */
    if (get_call_result_type(fcinfo, NULL, &tupdesc) != TYPEFUNC_COMPOSITE)
        ereport(ERROR,
                {errcode(ERRCODE_FEATURE_NOT_SUPPORTED),
                 errmsg("function returning record called in context "
                             "that cannot accept type record");});

    /* generate attribute metadata needed later to produce tuples from raw
     * C strings
     */
    attinmeta = TupleDescGetAttInMetadata(tupdesc);
    funcctx->attinmeta = attinmeta;

    MemoryContextSwitchTo(oldcontext);
}

/* stuff done on every call of the function */
funcctx = SRF_PERCALL_SETUP();

call_cntr = funcctx->call_cntr;
max_calls = funcctx->max_calls;
attinmeta = funcctx->attinmeta;

if (call_cntr < max_calls)    /* do when there is more left to send */
{
    char **values;
    HeapTuple tuple;
    Datum result;

    /* Prepare a values array for building the returned tuple.
     * This should be an array of C strings which will
     * be processed later by the type input functions.
     */
    values = (char **) palloc(3 * sizeof(char *));
    values[0] = (char *) palloc(16 * sizeof(char));
    values[1] = (char *) palloc(16 * sizeof(char));
    values[2] = (char *) palloc(16 * sizeof(char));

    snprintf(values[0], 16, "%d", 1 * PG_GETARG_INT32(1));
    snprintf(values[1], 16, "%d", 2 * PG_GETARG_INT32(1));
    snprintf(values[2], 16, "%d", 3 * PG_GETARG_INT32(1));
/* build a tuple */
tuple = BuildTupleFromCStrings(attinmeta, values);

/* make the tuple into a datum */
result = HeapTupleGetDatum(tuple);

/* clean up (this is not really necessary) */
pfree(values[0]);
pfree(values[1]);
pfree(values[2]);
pfree(values);

SRF_RETURN_NEXT(funcctx, result);
}
else /* do when there is no more left */
{
    SRF_RETURN_DONE(funcctx);
}

One way to declare this function in SQL is:

CREATE TYPE __retcomposite AS (f1 integer, f2 integer, f3 integer);

CREATE OR REPLACE FUNCTION retcomposite(integer, integer)
    RETURNS SETOF __retcomposite
    AS 'filename', 'retcomposite'
    LANGUAGE C IMMUTABLE STRICT;

A different way is to use OUT parameters:

CREATE OR REPLACE FUNCTION retcomposite(IN integer, IN integer,
    OUT f1 integer, OUT f2 integer, OUT f3 integer)
    RETURNS SETOF record
    AS 'filename', 'retcomposite'
    LANGUAGE C IMMUTABLE STRICT;

Notice that in this method the output type of the function is formally an anonymous record type.
The directory contrib/tablefunc in the source distribution contains more examples of set-returning functions.

34.9.11. Polymorphic Arguments and Return Types

C-language functions can be declared to accept and return the polymorphic types anyelement, anyarray, anynonarray, and anyenum. See Section 34.2.5 for a more detailed explanation of polymorphic functions. When function arguments or return types are defined as polymorphic types, the function author cannot know in advance what data type it will be called with, or need to return. There are two routines provided in fmgr.h to allow a version-1 C function to discover the actual data types of its arguments and the type it is expected to return. The routines are called get_fn_expr_rettype(FmgrInfo *flinfo) and get_fn_expr_argtype(FmgrInfo *flinfo, int argnum). They return the result or argument type OID, or InvalidOid if the information is not available. The structure flinfo is normally accessed as fcline->flinfo. The parameter argnum is zero based. get_call_result_type can also be used as an alternative to get_fn_expr_rettype.
For example, suppose we want to write a function to accept a single element of any type, and return a one-dimensional array of that type:

```c
PG_FUNCTION_INFO_V1(make_array);
Datum
make_array(PG_FUNCTION_ARGS)
{
    ArrayType *result;
    Oid    element_type = get_fn_expr_argtype(fcinfo->flinfo, 0);
    Datum  element;
    bool   isnull;
    int16  typlen;
    bool   typbyval;
    char   typalign;
    int    ndims;
    int    dims[MAXDIM];
    int    lbs[MAXDIM];

    if (!OidIsValid(element_type))
        elog(ERROR, "could not determine data type of input");

    /* get the provided element, being careful in case it’s NULL */
    isnull = PG_ARGISNULL(0);
    if (isnull)
        element = (Datum) 0;
    else
        element = PG_GETARG_DATUM(0);

    /* we have one dimension */
    ndims = 1;
    /* and one element */
    dims[0] = 1;
    /* and lower bound is 1 */
    lbs[0] = 1;

    /* get required info about the element type */
    get_typlenbyvalalign(element_type, &typlen, &typbyval, &typalign);

    /* now build the array */
    result = construct_md_array(&element, &isnull, ndims, dims, lbs,
                                element_type, typlen, typbyval, typalign);

    PG_RETURN_ARRAYTYPE_P(result);
}
```

The following command declares the function `make_array` in SQL:

```sql
CREATE FUNCTION make_array(anyelement) RETURNS anyarray
AS 'DIRECTORY/funcs', 'make_array'
LANGUAGE C IMMUTABLE;
```
34.9.12. Shared Memory and LWLocks

Add-ins can reserve LWLocks and an allocation of shared memory on server startup. The add-in’s shared library must be preloaded by specifying it in shared_preload_libraries. Shared memory is reserved by calling:

```c
void RequestAddinShmemSpace(int size)
```

from your \_PG\_init function.

LWLocks are reserved by calling:

```c
void RequestAddinLWLocks(int n)
```

from \_PG\_init.

To avoid possible race-conditions, each backend should use the LWLock `AddinShmemInitLock` when connecting to and initializing its allocation of shared memory, as shown here:

```c
static mystruct *ptr = NULL;
if (!ptr)
{
  bool found;
  LWLockAcquire(AddinShmemInitLock, LW_EXCLUSIVE);
  ptr = ShmemInitStruct("my struct name", size, &found);
  if (!ptr)
    elog(ERROR, "out of shared memory");
  if (!found)
    {
      initialize contents of shmem area;
      acquire any requested LWLocks using:
      ptr->mylockid = LWLockAssign();
    }
  LWLockRelease(AddinShmemInitLock);
}
```

34.10. User-Defined Aggregates

Aggregate functions in PostgreSQL are expressed in terms of state values and state transition functions. That is, an aggregate operates using a state value that is updated as each successive input row is processed. To define a new aggregate function, one selects a data type for the state value, an initial value for the state, and a state transition function. The state transition function is just an ordinary function that could also be used outside the context of the aggregate. A final function can also be specified, in case the desired result of the aggregate is different from the data that needs to be kept in the running state value.

Thus, in addition to the argument and result data types seen by a user of the aggregate, there is an internal state-value data type that might be different from both the argument and result types.

If we define an aggregate that does not use a final function, we have an aggregate that computes a running function of the column values from each row. `sum` is an example of this kind of aggregate. `sum` starts at zero and always adds the current row’s value to its running total. For example, if we
want to make a `sum` aggregate to work on a data type for complex numbers, we only need the addition function for that data type. The aggregate definition would be:

```sql
CREATE AGGREGATE sum (complex)
(
    sfunc = complex_add,
    stype = complex,
    initcond = '(0,0)'
);
```

SELECT sum(a) FROM test_complex;

<table>
<thead>
<tr>
<th>sum</th>
</tr>
</thead>
<tbody>
<tr>
<td>(34, 53.9)</td>
</tr>
</tbody>
</table>

(Notice that we are relying on function overloading: there is more than one aggregate named `sum`, but PostgreSQL can figure out which kind of sum applies to a column of type `complex`.)

The above definition of `sum` will return zero (the initial state condition) if there are no nonnull input values. Perhaps we want to return null in that case instead — the SQL standard expects `sum` to behave that way. We can do this simply by omitting the `initcond` phrase, so that the initial state condition is null. Ordinarily this would mean that the `sfunc` would need to check for a null state-condition input. But for `sum` and some other simple aggregates like `max` and `min`, it is sufficient to insert the first nonnull input value into the state variable and then start applying the transition function at the second nonnull input value. PostgreSQL will do that automatically if the initial condition is null and the transition function is marked “strict” (i.e., not to be called for null inputs).

Another bit of default behavior for a “strict” transition function is that the previous state value is retained unchanged whenever a null input value is encountered. Thus, null values are ignored. If you need some other behavior for null inputs, do not declare your transition function as strict; instead code it to test for null inputs and do whatever is needed.

`avg` (average) is a more complex example of an aggregate. It requires two pieces of running state: the sum of the inputs and the count of the number of inputs. The final result is obtained by dividing these quantities. Average is typically implemented by using an array as the state value. For example, the built-in implementation of `avg(float8)` looks like:

```sql
CREATE AGGREGATE avg (float8)
(
    sfunc = float8_accum,
    stype = float8[],
    finalfunc = float8_avg,
    initcond = '{0,0}'
);
```

(`float8_accum` requires a three-element array, not just two elements, because it accumulates the sum of squares as well as the sum and count of the inputs. This is so that it can be used for some other aggregates besides `avg`.)

Aggregate functions can use polymorphic state transition functions or final functions, so that the same functions can be used to implement multiple aggregates. See Section 34.2.5 for an explanation of polymorphic functions. Going a step further, the aggregate function itself can be specified with polymorphic input type(s) and state type, allowing a single aggregate definition to serve for multiple input data types. Here is an example of a polymorphic aggregate:

```sql
CREATE AGGREGATE array_accum (anyelement)
```
Chapter 34. Extending SQL

```c
(sfunc = array_append,
 stype = anyarray,
 initcond = '{}');
```

Here, the actual state type for any aggregate call is the array type having the actual input type as elements.

Here’s the output using two different actual data types as arguments:

```sql
SELECT attrelid::regclass, array_accum(attname)
FROM pg_attribute
WHERE attnum > 0 AND attrelid = 'pg_tablespace'::regclass
GROUP BY attrelid;
```

```
+---------------------------------------+-----------------------------+
<table>
<thead>
<tr>
<th>attrelid</th>
<th>array_accum</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_tablespace</td>
<td>{spcname, spcowner, spclocation, spcacl}</td>
</tr>
</tbody>
</table>
+--------------------------+-----------------------------+
(1 row)
```

```sql
SELECT attrelid::regclass, array_accum(atttypid)
FROM pg_attribute
WHERE attnum > 0 AND attrelid = 'pg_tablespace'::regclass
GROUP BY attrelid;
```

```
+---------------------------------------+-----------------------------+
<table>
<thead>
<tr>
<th>attrelid</th>
<th>array_accum</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_tablespace</td>
<td>{19, 26, 25, 1034}</td>
</tr>
</tbody>
</table>
+--------------------------+-----------------------------+
(1 row)
```

A function written in C can detect that it is being called as an aggregate transition or final function by seeing if it was passed an `AggState` node as the function call “context”, for example by:

```c
if (fcinfo->context && IsA(fcinfo->context, AggState))
```

One reason for checking this is that when it is true, the first input must be a temporary transition value and can therefore safely be modified in-place rather than allocating a new copy. (This is the only case where it is safe for a function to modify a pass-by-reference input.) See `int8inc()` for an example.

For further details see the `CREATE AGGREGATE` command.

34.11. User-Defined Types

As described in Section 34.2, PostgreSQL can be extended to support new data types. This section describes how to define new base types, which are data types defined below the level of the SQL language. Creating a new base type requires implementing functions to operate on the type in a low-level language, usually C.

The examples in this section can be found in `complex.sql` and `complex.c` in the `src/tutorial` directory of the source distribution. See the `README` file in that directory for instructions about running the examples.

A user-defined type must always have input and output functions. These functions determine how the type appears in strings (for input by the user and output to the user) and how the type is organized in
memory. The input function takes a null-terminated character string as its argument and returns the internal (in memory) representation of the type. The output function takes the internal representation of the type as argument and returns a null-terminated character string. If we want to do anything more with the type than merely store it, we must provide additional functions to implement whatever operations we’d like to have for the type.

Suppose we want to define a type complex that represents complex numbers. A natural way to represent a complex number in memory would be the following C structure:

```c
typedef struct Complex {
  double x;
  double y;
} Complex;
```

We will need to make this a pass-by-reference type, since it’s too large to fit into a single Datum value.

As the external string representation of the type, we choose a string of the form \((x, y)\).

The input and output functions are usually not hard to write, especially the output function. But when defining the external string representation of the type, remember that you must eventually write a complete and robust parser for that representation as your input function. For instance:

```c
PG_FUNCTION_INFO_V1(complex_in);

Datum complex_in(PG_FUNCTION_ARGS)
{
  char *str = PG_GETARG_CSTRING(0);
  double x,
          y;
  Complex *result;

  if (sscanf(str, " ( %lf , %lf )", &x, &y) != 2)
    ereport(ERROR,
            (errcode(ERRCODE_INVALID_TEXT_REPRESENTATION),
            errmsg("invalid input syntax for complex: \"%s\"",
                    str)));

  result = (Complex *) palloc(sizeof(Complex));
  result->x = x;
  result->y = y;
  PG_RETURN_POINTER(result);
}
```

The output function can simply be:

```c
PG_FUNCTION_INFO_V1(complex_out);

Datum complex_out(PG_FUNCTION_ARGS)
{
  Complex *complex = (Complex *) PG_GETARG_POINTER(0);
  char *result;

  result = (char *) palloc(100);
  snprintf(result, 100, "(%g,%g)", complex->x, complex->y);
  PG_RETURN_CSTRING(result);
}
```
You should be careful to make the input and output functions inverses of each other. If you do not, you will have severe problems when you need to dump your data into a file and then read it back in. This is a particularly common problem when floating-point numbers are involved.

Optionally, a user-defined type can provide binary input and output routines. Binary I/O is normally faster but less portable than textual I/O. As with textual I/O, it is up to you to define exactly what the external binary representation is. Most of the built-in data types try to provide a machine-independent binary representation. For complex, we will piggy-back on the binary I/O converters for type float8:

```c
PG_FUNCTION_INFO_V1(complex_recv);

Datum
complex_recv(PG_FUNCTION_ARGS)
{
    StringInfo  buf = (StringInfo) PG_GETARG_POINTER(0);
    Complex      *result;

    result = (Complex *) palloc(sizeof(Complex));
    result->x = pq_getmsgfloat8(buf);
    result->y = pq_getmsgfloat8(buf);
    PG_RETURN_POINTER(result);
}

PG_FUNCTION_INFO_V1(complex_send);

Datum
complex_send(PG_FUNCTION_ARGS)
{
    Complex      *complex = (Complex *) PG_GETARG_POINTER(0);
    StringInfoData buf;

    pq_begintypsend(&buf);
    pq_sendfloat8(&buf, complex->x);
    pq_sendfloat8(&buf, complex->y);
    PG_RETURN_BYTEA_P(pq_endtypsend(&buf));
}
```

Once we have written the I/O functions and compiled them into a shared library, we can define the complex type in SQL. First we declare it as a shell type:

```sql
CREATE TYPE complex;
```

This serves as a placeholder that allows us to reference the type while defining its I/O functions. Now we can define the I/O functions:

```sql
CREATE FUNCTION complex_in(cstring)
    RETURNS complex
    AS 'filename'
    LANGUAGE C IMMUTABLE STRICT;

CREATE FUNCTION complex_out(complex)
    RETURNS cstring
    AS 'filename'
```
Chapter 34. Extending SQL

```
LANGUAGE C IMMUTABLE STRICT;

CREATE FUNCTION complex_recv(internal)
RETURNS complex
AS 'filename'
LANGUAGE C IMMUTABLE STRICT;

CREATE FUNCTION complex_send(complex)
RETURNS bytea
AS 'filename'
LANGUAGE C IMMUTABLE STRICT;
```

Finally, we can provide the full definition of the data type:

```
CREATE TYPE complex (
    internallength = 16,
    input = complex_in,
    output = complex_out,
    receive = complex_recv,
    send = complex_send,
    alignment = double
);
```

When you define a new base type, PostgreSQL automatically provides support for arrays of that type. The array type typically has the same name as the base type with the underscore character (\_) prepended.

Once the data type exists, we can declare additional functions to provide useful operations on the data type. Operators can then be defined atop the functions, and if needed, operator classes can be created to support indexing of the data type. These additional layers are discussed in following sections.

If the values of your data type vary in size (in internal form), you should make the data type TOASTable (see Section 53.2). You should do this even if the data are always too small to be compressed or stored externally, because TOAST can save space on small data too, by reducing header overhead.

To do this, the internal representation must follow the standard layout for variable-length data: the first four bytes must be a char[4] field which is never accessed directly (customarily named vl_len_\_). You must use SET_VARSIZE() to store the size of the datum in this field and VARSIZE() to retrieve it. The C functions operating on the data type must always be careful to unpack any toasted values they are handed, by using PG\_DETOAST\_DATUM. (This detail is customarily hidden by defining type-specific GETARG\_DATATYPE\_P macros.) Then, when running the CREATE TYPE command, specify the internal length as variable and select the appropriate storage option.

If the alignment is unimportant (either just for a specific function or because the data type specifies byte alignment anyways) then it’s possible to avoid some of the overhead of PG\_DETOAST\_DATUM. You can use PG\_DETOAST\_DATUM\_PACKED instead (customarily hidden by defining a GETARG\_DATATYPE\_PP macro) and using the macros VARSIZE\_ANY\_EXHDR and VARDATA\_ANY to access a potentially-packed datum. Again, the data returned by these macros is not aligned even if the data type definition specifies an alignment. If the alignment is important you must go through the regular PG\_DETOAST\_DATUM interface.

**Note:** Older code frequently declares vl_len_ as an int32 field instead of char[4]. This is OK as long as the struct definition has other fields that have at least int32 alignment. But it is dangerous to use such a struct definition when working with a potentially unaligned datum; the compiler may
take it as license to assume the datum actually is aligned, leading to core dumps on architectures
that are strict about alignment.

For further details see the description of the CREATE TYPE command.

### 34.12. User-Defined Operators

Every operator is “syntactic sugar” for a call to an underlying function that does the real work; so
you must first create the underlying function before you can create the operator. However, an operator
is not merely syntactic sugar, because it carries additional information that helps the query planner
optimize queries that use the operator. The next section will be devoted to explaining that additional
information.

PostgreSQL supports left unary, right unary, and binary operators. Operators can be overloaded; that
is, the same operator name can be used for different operators that have different numbers and types
of operands. When a query is executed, the system determines the operator to call from the number
and types of the provided operands.

Here is an example of creating an operator for adding two complex numbers. We assume we’ve
already created the definition of type complex (see Section 34.11). First we need a function that does
the work, then we can define the operator:

```sql
CREATE FUNCTION complex_add(complex, complex)
    RETURNS complex
    AS 'filename', 'complex_add'
    LANGUAGE C IMMUTABLE STRICT;

CREATE OPERATOR + (
    leftarg = complex,
    rightarg = complex,
    procedure = complex_add,
    commutator = +
);
```

Now we could execute a query like this:

```sql
SELECT (a + b) AS c FROM test_complex;
```

```
c
(5.2,6.05)
(133.42,144.95)
```

We’ve shown how to create a binary operator here. To create unary operators, just omit one of
leftarg (for left unary) or rightarg (for right unary). The procedure clause and the argument
clauses are the only required items in CREATE OPERATOR. The commutator clause shown in the
example is an optional hint to the query optimizer. Further details about commutator and other opti-
mizer hints appear in the next section.
34.13. Operator Optimization Information

A PostgreSQL operator definition can include several optional clauses that tell the system useful things about how the operator behaves. These clauses should be provided whenever appropriate, because they can make for considerable speedups in execution of queries that use the operator. But if you provide them, you must be sure that they are right! Incorrect use of an optimization clause can result in slow queries, subtly wrong output, or other Bad Things. You can always leave out an optimization clause if you are not sure about it; the only consequence is that queries might run slower than they need to.

Additional optimization clauses might be added in future versions of PostgreSQL. The ones described here are all the ones that release 8.3.23 understands.

34.13.1. COMMUTATOR

The COMMUTATOR clause, if provided, names an operator that is the commutator of the operator being defined. We say that operator A is the commutator of operator B if (x A y) equals (y B x) for all possible input values x, y. Notice that B is also the commutator of A. For example, operators < and > for a particular data type are usually each others’ commutators, and operator + is usually commutative with itself. But operator – is usually not commutative with anything.

The left operand type of a commutable operator is the same as the right operand type of its commutator, and vice versa. So the name of the commutator operator is all that PostgreSQL needs to be given to look up the commutator, and that’s all that needs to be provided in the COMMUTATOR clause.

It’s critical to provide commutator information for operators that will be used in indexes and join clauses, because this allows the query optimizer to “flip around” such a clause to the forms needed for different plan types. For example, consider a query with a WHERE clause like tab1.x = tab2.y, where tab1.x and tab2.y are of a user-defined type, and suppose that tab2.y is indexed. The optimizer cannot generate an index scan unless it can determine how to flip the clause around to tab2.y = tab1.x, because the index-scan machinery expects to see the indexed column on the left of the operator it is given. PostgreSQL will not simply assume that this is a valid transformation — the creator of the = operator must specify that it is valid, by marking the operator with commutator information.

When you are defining a self-commutative operator, you just do it. When you are defining a pair of commutative operators, things are a little trickier: how can the first one to be defined refer to the other one, which you haven’t defined yet? There are two solutions to this problem:

• One way is to omit the COMMUTATOR clause in the first operator that you define, and then provide one in the second operator’s definition. Since PostgreSQL knows that commutative operators come in pairs, when it sees the second definition it will automatically go back and fill in the missing COMMUTATOR clause in the first definition.

• The other, more straightforward way is just to include COMMUTATOR clauses in both definitions. When PostgreSQL processes the first definition and realizes that COMMUTATOR refers to a nonexistent operator, the system will make a dummy entry for that operator in the system catalog. This dummy entry will have valid data only for the operator name, left and right operand types, and result type, since that’s all that PostgreSQL can deduce at this point. The first operator’s catalog entry will link to this dummy entry. Later, when you define the second operator, the system updates the dummy entry with the additional information from the second definition. If you try to use the dummy operator before it’s been filled in, you’ll just get an error message.
34.13.2. NEGATOR

The **NEGATOR** clause, if provided, names an operator that is the negator of the operator being defined. We say that operator A is the negator of operator B if both return Boolean results and (x A y) equals NOT (x B y) for all possible inputs x, y. Notice that B is also the negator of A. For example, < and >= are a negator pair for most data types. An operator can never validly be its own negator.

Unlike commutators, a pair of unary operators could validly be marked as each others’ negators; that would mean (A x) equals NOT (B x) for all x, or the equivalent for right unary operators.

An operator’s negator must have the same left and/or right operand types as the operator to be defined, so just as with **COMMUTATOR**, only the operator name need be given in the **NEGATOR** clause.

Providing a negator is very helpful to the query optimizer since it allows expressions like NOT (x = y) to be simplified into x <> y. This comes up more often than you might think, because NOT operations can be inserted as a consequence of other rearrangements.

Pairs of negator operators can be defined using the same methods explained above for commutator pairs.

34.13.3. RESTRICT

The **RESTRICT** clause, if provided, names a restriction selectivity estimation function for the operator. (Note that this is a function name, not an operator name.) **RESTRICT** clauses only make sense for binary operators that return boolean. The idea behind a restriction selectivity estimator is to guess what fraction of the rows in a table will satisfy a **WHERE**-clause condition of the form:

```
column OP constant
```

for the current operator and a particular constant value. This assists the optimizer by giving it some idea of how many rows will be eliminated by **WHERE** clauses that have this form. (What happens if the constant is on the left, you might be wondering? Well, that’s one of the things that **COMMUTATOR** is for...)

Writing new restriction selectivity estimation functions is far beyond the scope of this chapter, but fortunately you can usually just use one of the system’s standard estimators for many of your own operators. These are the standard restriction estimators:

```
eqsel for =
eqsel for <>
scalarltssel for < or <=
scalargtssel for > or >-
```

It might seem a little odd that these are the categories, but they make sense if you think about it. = will typically accept only a small fraction of the rows in a table; <> will typically reject only a small fraction. < will accept a fraction that depends on where the given constant falls in the range of values for that table column (which, it just so happens, is information collected by **ANALYZE** and made available to the selectivity estimator). <= will accept a slightly larger fraction than < for the same comparison constant, but they’re close enough to not be worth distinguishing, especially since we’re not likely to do better than a rough guess anyhow. Similar remarks apply to > and >-.

You can frequently get away with using either **eqsel** or **neqsel** for operators that have very high or very low selectivity, even if they aren’t really equality or inequality. For example, the approximate-equality geometric operators use **eqsel** on the assumption that they’ll usually only match a small fraction of the entries in a table.
You can use `scalarltsel` and `scalargtssel` for comparisons on data types that have some sensible means of being converted into numeric scalars for range comparisons. If possible, add the data type to those understood by the function `convert_to_scalar()` in `src/backend/utils/adt/selfuncs.c`. (Eventually, this function should be replaced by per-data-type functions identified through a column of the pg_type system catalog; but that hasn’t happened yet.) If you do not do this, things will still work, but the optimizer’s estimates won’t be as good as they could be.

There are additional selectivity estimation functions designed for geometric operators in `src/backend/utils/adt/geo_selfuncs.c`: `areasel`, `positionsel`, and `contsel`. At this writing these are just stubs, but you might want to use them (or even better, improve them) anyway.

### 34.13.4. JOIN

The `JOIN` clause, if provided, names a join selectivity estimation function for the operator. (Note that this is a function name, not an operator name.) `JOIN` clauses only make sense for binary operators that return boolean. The idea behind a join selectivity estimator is to guess what fraction of the rows in a pair of tables will satisfy a `WHERE`-clause condition of the form:

```
  table1.column1 OP table2.column2
```

for the current operator. As with the `RESTRIC`T clause, this helps the optimizer very substantially by letting it figure out which of several possible join sequences is likely to take the least work.

As before, this chapter will make no attempt to explain how to write a join selectivity estimator function, but will just suggest that you use one of the standard estimators if one is applicable:

- `eqjoinsel` for `=`
- `neqjoinsel` for `<>
- `scalarltjoinsel` for `< or `<=`
- `scalargtjoinsel` for `>` or `>=`
- `areajoinsel` for 2D area-based comparisons
- `positionjoinsel` for 2D position-based comparisons
- `contjoinsel` for 2D containment-based comparisons

### 34.13.5. HASHES

The `HASHES` clause, if present, tells the system that it is permissible to use the hash join method for a join based on this operator. `HASHES` only makes sense for a binary operator that returns boolean, and in practice the operator must represent equality for some data type or pair of data types.

The assumption underlying hash join is that the join operator can only return true for pairs of left and right values that hash to the same hash code. If two values get put in different hash buckets, the join will never compare them at all, implicitly assuming that the result of the join operator must be false. So it never makes sense to specify `HASHES` for operators that do not represent some form of equality. In most cases it is only practical to support hashing for operators that take the same data type on both sides. However, sometimes it is possible to design compatible hash functions for two or more data types; that is, functions that will generate the same hash codes for “equal” values, even though the values have different representations. For example, it’s fairly simple to arrange this property when hashing integers of different widths.
To be marked HASHES, the join operator must appear in a hash index operator family. This is not enforced when you create the operator, since of course the referencing operator family couldn’t exist yet. But attempts to use the operator in hash joins will fail at run time if no such operator family exists. The system needs the operator family to find the data-type-specific hash function(s) for the operator’s input data type(s). Of course, you must also create suitable hash functions before you can create the operator family.

Care should be exercised when preparing a hash function, because there are machine-dependent ways in which it might fail to do the right thing. For example, if your data type is a structure in which there might be uninteresting pad bits, you cannot simply pass the whole structure to hash_any. (Unless you write your other operators and functions to ensure that the unused bits are always zero, which is the recommended strategy.) Another example is that on machines that meet the IEEE floating-point standard, negative zero and positive zero are different values (different bit patterns) but they are defined to compare equal. If a float value might contain negative zero then extra steps are needed to ensure it generates the same hash value as positive zero.

A hash-joinable operator must have a commutator (itself if the two operand data types are the same, or a related equality operator if they are different) that appears in the same operator family. If this is not the case, planner errors might occur when the operator is used. Also, it is a good idea (but not strictly required) for a hash operator family that supports multiple data types to provide equality operators for every combination of the data types; this allows better optimization.

**Note:** The function underlying a hash-joinable operator must be marked immutable or stable. If it is volatile, the system will never attempt to use the operator for a hash join.

**Note:** If a hash-joinable operator has an underlying function that is marked strict, the function must also be complete: that is, it should return true or false, never null, for any two nonnull inputs. If this rule is not followed, hash-optimization of IN operations might generate wrong results. (Specifically, IN might return false where the correct answer according to the standard would be null, or it might yield an error complaining that it wasn’t prepared for a null result.)

### 34.13.6. MERGES

The MERGES clause, if present, tells the system that it is permissible to use the merge-join method for a join based on this operator. MERGES only makes sense for a binary operator that returns boolean, and in practice the operator must represent equality for some data type or pair of data types.

Merge join is based on the idea of sorting the left- and right-hand tables into order and then scanning them in parallel. So, both data types must be capable of being fully ordered, and the join operator must be one that can only succeed for pairs of values that fall at the “same place” in the sort order. In practice this means that the join operator must behave like equality. But it is possible to merge-join two distinct data types so long as they are logically compatible. For example, the smallint-versus-integer equality operator is merge-joinable. We only need sorting operators that will bring both data types into a logically compatible sequence.

To be marked MERGES, the join operator must appear as an equality member of a btree index operator family. This is not enforced when you create the operator, since of course the referencing operator family couldn’t exist yet. But the operator will not actually be used for merge joins unless a matching operator family can be found. The MERGES flag thus acts as a hint to the planner that it’s worth looking for a matching operator family.
A merge-joinable operator must have a commutator (itself if the two operand data types are the same, or a related equality operator if they are different) that appears in the same operator family. If this is not the case, planner errors might occur when the operator is used. Also, it is a good idea (but not strictly required) for a btree operator family that supports multiple data types to provide equality operators for every combination of the data types; this allows better optimization.

**Note:** The function underlying a merge-joinable operator must be marked immutable or stable. If it is volatile, the system will never attempt to use the operator for a merge join.

### 34.14. Interfacing Extensions To Indexes

The procedures described thus far let you define new types, new functions, and new operators. However, we cannot yet define an index on a column of a new data type. To do this, we must define an operator class for the new data type. Later in this section, we will illustrate this concept in an example: a new operator class for the B-tree index method that stores and sorts complex numbers in ascending absolute value order.

Operator classes can be grouped into operator families to show the relationships between semantically compatible classes. When only a single data type is involved, an operator class is sufficient, so we’ll focus on that case first and then return to operator families.

#### 34.14.1. Index Methods and Operator Classes

The `pg_am` table contains one row for every index method (internally known as access method). Support for regular access to tables is built into PostgreSQL, but all index methods are described in `pg_am`. It is possible to add a new index method by defining the required interface routines and then creating a row in `pg_am` — but that is beyond the scope of this chapter (see Chapter 50).

The routines for an index method do not directly know anything about the data types that the index method will operate on. Instead, an operator class identifies the set of operations that the index method needs to use to work with a particular data type. Operator classes are so called because one thing they specify is the set of WHERE-clause operators that can be used with an index (i.e., can be converted into an index-scan qualification). An operator class can also specify some support procedures that are needed by the internal operations of the index method, but do not directly correspond to any WHERE-clause operator that can be used with the index.

It is possible to define multiple operator classes for the same data type and index method. By doing this, multiple sets of indexing semantics can be defined for a single data type. For example, a B-tree index requires a sort ordering to be defined for each data type it works on. It might be useful for a complex-number data type to have one B-tree operator class that sorts the data by complex absolute value, another that sorts by real part, and so on. Typically, one of the operator classes will be deemed most commonly useful and will be marked as the default operator class for that data type and index method.

The same operator class name can be used for several different index methods (for example, both B-tree and hash index methods have operator classes named `int4_ops`), but each such class is an independent entity and must be defined separately.
34.14.2. Index Method Strategies

The operators associated with an operator class are identified by “strategy numbers”, which serve to identify the semantics of each operator within the context of its operator class. For example, B-trees impose a strict ordering on keys, lesser to greater, and so operators like “less than” and “greater than or equal to” are interesting with respect to a B-tree. Because PostgreSQL allows the user to define operators, PostgreSQL cannot look at the name of an operator (e.g., < or >=) and tell what kind of comparison it is. Instead, the index method defines a set of “strategies”, which can be thought of as generalized operators. Each operator class specifies which actual operator corresponds to each strategy for a particular data type and interpretation of the index semantics.

The B-tree index method defines five strategies, shown in Table 34-2.

Table 34-2. B-tree Strategies

<table>
<thead>
<tr>
<th>Operation</th>
<th>Strategy Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>less than</td>
<td>1</td>
</tr>
<tr>
<td>less than or equal</td>
<td>2</td>
</tr>
<tr>
<td>equal</td>
<td>3</td>
</tr>
<tr>
<td>greater than or equal</td>
<td>4</td>
</tr>
<tr>
<td>greater than</td>
<td>5</td>
</tr>
</tbody>
</table>

Hash indexes support only equality comparisons, and so they use only one strategy, shown in Table 34-3.

Table 34-3. Hash Strategies

<table>
<thead>
<tr>
<th>Operation</th>
<th>Strategy Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>equal</td>
<td>1</td>
</tr>
</tbody>
</table>

GiST indexes are more flexible: they do not have a fixed set of strategies at all. Instead, the “consistency” support routine of each particular GiST operator class interprets the strategy numbers however it likes. As an example, several of the built-in GiST index operator classes index two-dimensional geometric objects, providing the “R-tree” strategies shown in Table 34-4. Four of these are true two-dimensional tests (overlaps, same, contains, contained by); four of them consider only the X direction; and the other four provide the same tests in the Y direction.

Table 34-4. GiST Two-Dimensional “R-tree” Strategies

<table>
<thead>
<tr>
<th>Operation</th>
<th>Strategy Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>strictly left of</td>
<td>1</td>
</tr>
<tr>
<td>does not extend to right of</td>
<td>2</td>
</tr>
<tr>
<td>overlaps</td>
<td>3</td>
</tr>
<tr>
<td>does not extend to left of</td>
<td>4</td>
</tr>
<tr>
<td>strictly right of</td>
<td>5</td>
</tr>
<tr>
<td>same</td>
<td>6</td>
</tr>
<tr>
<td>contains</td>
<td>7</td>
</tr>
<tr>
<td>contained by</td>
<td>8</td>
</tr>
<tr>
<td>does not extend above</td>
<td>9</td>
</tr>
</tbody>
</table>
GIN indexes are similar to GiST indexes in flexibility: they don’t have a fixed set of strategies. Instead the support routines of each operator class interpret the strategy numbers according to the operator class’s definition. As an example, the strategy numbers used by the built-in operator classes for arrays are shown in Table 34-5.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Strategy Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>strictly below</td>
<td>10</td>
</tr>
<tr>
<td>strictly above</td>
<td>11</td>
</tr>
<tr>
<td>does not extend below</td>
<td>12</td>
</tr>
</tbody>
</table>

Table 34-5. GIN Array Strategies

Notice that all strategy operators return Boolean values. In practice, all operators defined as index method strategies must return type `boolean`, since they must appear at the top level of a `WHERE` clause to be used with an index.

### 34.14.3. Index Method Support Routines

Strategies aren’t usually enough information for the system to figure out how to use an index. In practice, the index methods require additional support routines in order to work. For example, the B-tree index method must be able to compare two keys and determine whether one is greater than, equal to, or less than the other. Similarly, the hash index method must be able to compute hash codes for key values. These operations do not correspond to operators used in qualifications in SQL commands; they are administrative routines used by the index methods, internally.

Just as with strategies, the operator class identifies which specific functions should play each of these roles for a given data type and semantic interpretation. The index method defines the set of functions it needs, and the operator class identifies the correct functions to use by assigning them to the “support function numbers” specified by the index method.

B-trees require a single support function, shown in Table 34-6.

<table>
<thead>
<tr>
<th>Function</th>
<th>Support Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>Compare two keys and return an integer less than zero, zero, or greater than zero, indicating whether the first key is less than, equal to, or greater than the second</td>
<td>1</td>
</tr>
</tbody>
</table>

Hash indexes likewise require one support function, shown in Table 34-7.

Table 34-7. Hash Support Functions
GiST indexes require seven support functions, shown in Table 34-8.

### Table 34-8. GiST Support Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Support Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>consistent - determine whether key satisfies the query qualifier</td>
<td>1</td>
</tr>
<tr>
<td>union - compute union of a set of keys</td>
<td>2</td>
</tr>
<tr>
<td>compress - compute a compressed representation of a key or value to be indexed</td>
<td>3</td>
</tr>
<tr>
<td>decompress - compute a decompressed representation of a compressed key</td>
<td>4</td>
</tr>
<tr>
<td>penalty - compute penalty for inserting new key into subtree with given subtree’s key</td>
<td>5</td>
</tr>
<tr>
<td>picksplit - determine which entries of a page are to be moved to the new page and compute the union keys for resulting pages</td>
<td>6</td>
</tr>
<tr>
<td>equal - compare two keys and return true if they are equal</td>
<td>7</td>
</tr>
</tbody>
</table>

GIN indexes require four support functions, shown in Table 34-9.

### Table 34-9. GIN Support Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Support Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>compare - compare two keys and return an integer less than zero, zero, or greater than zero, indicating whether the first key is less than, equal to, or greater than the second</td>
<td>1</td>
</tr>
<tr>
<td>extractValue - extract keys from a value to be indexed</td>
<td>2</td>
</tr>
<tr>
<td>extractQuery - extract keys from a query condition</td>
<td>3</td>
</tr>
<tr>
<td>consistent - determine whether value matches query condition</td>
<td>4</td>
</tr>
</tbody>
</table>

Unlike strategy operators, support functions return whichever data type the particular index method expects; for example in the case of the comparison function for B-trees, a signed integer. The number and types of the arguments to each support function are likewise dependent on the index method. For B-tree and hash the support functions take the same input data types as do the operators included in the operator class, but this is not the case for most GIN and GiST support functions.

### 34.14.4. An Example

Now that we have seen the ideas, here is the promised example of creating a new operator
class. (You can find a working copy of this example in src/tutorial/complex.c and src/tutorial/complex.sql in the source distribution.) The operator class encapsulates operators that sort complex numbers in absolute value order, so we choose the name complex_abs_ops. First, we need a set of operators. The procedure for defining operators was discussed in Section 34.12. For an operator class on B-trees, the operators we require are:

- absolute-value less-than (strategy 1)
- absolute-value less-than-or-equal (strategy 2)
- absolute-value equal (strategy 3)
- absolute-value greater-than-or-equal (strategy 4)
- absolute-value greater-than (strategy 5)

The least error-prone way to define a related set of comparison operators is to write the B-tree comparison support function first, and then write the other functions as one-line wrappers around the support function. This reduces the odds of getting inconsistent results for corner cases. Following this approach, we first write:

```c
#define Mag(c) ((c)->x*(c)->x + (c)->y*(c)->y)
static int complex_abs_cmp_internal(Complex *a, Complex *b)
{
    double amag = Mag(a), bmag = Mag(b);
    if (amag < bmag)
        return -1;
    if (amag > bmag)
        return 1;
    return 0;
}
```

Now the less-than function looks like:

```c
PG_FUNCTION_INFO_V1(complex_abs_lt);
Datum complex_abs_lt(PG_FUNCTION_ARGS)
{
    Complex *a = (Complex *) PG_GETARG_POINTER(0);
    Complex *b = (Complex *) PG_GETARG_POINTER(1);
    PG_RETURN_BOOL(complex_abs_cmp_internal(a, b) < 0);
}
```

The other four functions differ only in how they compare the internal function’s result to zero.

Next we declare the functions and the operators based on the functions to SQL:

```sql
CREATE FUNCTION complex_abs_lt(complex, complex) RETURNS bool
AS 'filename', 'complex_abs_lt'
LANGUAGE C IMMUTABLE STRICT;
CREATE OPERATOR < (
    leftarg = complex, rightarg = complex, procedure = complex_abs_lt,
    ....
)
commutator = >, negator = >=,
restrict = scalarltssel, join = scalarltojinsel
);

It is important to specify the correct commutator and negator operators, as well as suitable restriction
and join selectivity functions, otherwise the optimizer will be unable to make effective use of the
index. Note that the less-than, equal, and greater-than cases should use different selectivity functions.

Other things worth noting are happening here:

• There can only be one operator named, say, = and taking type complex for both operands. In this
case we don’t have any other operator = for complex, but if we were building a practical data
type we’d probably want = to be the ordinary equality operation for complex numbers (and not
the equality of the absolute values). In that case, we’d need to use some other operator name for
complex_abs_eq.

• Although PostgreSQL can cope with functions having the same SQL name as long as they have
different argument data types, C can only cope with one global function having a given name. So
we shouldn’t name the C function something simple like abs_eq. Usually it’s a good practice to
include the data type name in the C function name, so as not to conflict with functions for other
data types.

• We could have made the SQL name of the function abs_eq, relying on PostgreSQL to distinguish
it by argument data types from any other SQL function of the same name. To keep the example
simple, we make the function have the same names at the C level and SQL level.

The next step is the registration of the support routine required by B-trees. The example C code that
implements this is in the same file that contains the operator functions. This is how we declare the
function:

CREATE FUNCTION complex_abs_cmp(complex, complex)
RETURNS integer
AS 'filename'
LANGUAGE C IMMUTABLE STRICT;

Now that we have the required operators and support routine, we can finally create the operator class:

CREATE OPERATOR CLASS complex_abs_ops
DEFAULT FOR TYPE complex USING btree AS
OPERATOR 1 <,
OPERATOR 2 <=,
OPERATOR 3 =,
OPERATOR 4 >=,
OPERATOR 5 >,
FUNCTION 1 complex_abs_cmp(complex, complex);

And we’re done! It should now be possible to create and use B-tree indexes on complex columns.
We could have written the operator entries more verbosely, as in:

OPERATOR 1 < (complex, complex),
but there is no need to do so when the operators take the same data type we are defining the operator class for.

The above example assumes that you want to make this new operator class the default B-tree operator class for the `complex` data type. If you don’t, just leave out the word `DEFAULT`.

### 34.14.5. Operator Classes and Operator Families

So far we have implicitly assumed that an operator class deals with only one data type. While there certainly can be only one data type in a particular index column, it is often useful to index operations that compare an indexed column to a value of a different data type. Also, if there is use for a cross-data-type operator in connection with an operator class, it is often the case that the other data type has a related operator class of its own. It is helpful to make the connections between related classes explicit, because this can aid the planner in optimizing SQL queries (particularly for B-tree operator classes, since the planner contains a great deal of knowledge about how to work with them).

To handle these needs, PostgreSQL uses the concept of an operator family. An operator family contains one or more operator classes, and can also contain indexable operators and corresponding support functions that belong to the family as a whole but not to any single class within the family. We say that such operators and functions are “loose” within the family, as opposed to being bound into a specific class. Typically each operator class contains single-data-type operators while cross-data-type operators are loose in the family.

All the operators and functions in an operator family must have compatible semantics, where the compatibility requirements are set by the index method. You might therefore wonder why bother to single out particular subsets of the family as operator classes; and indeed for many purposes the class divisions are irrelevant and the family is the only interesting grouping. The reason for defining operator classes is that they specify how much of the family is needed to support any particular index. If there is an index using an operator class, then that operator class cannot be dropped without dropping the index — but other parts of the operator family, namely other operator classes and loose operators, could be dropped. Thus, an operator class should be specified to contain the minimum set of operators and functions that are reasonably needed to work with an index on a specific data type, and then related but non-essential operators can be added as loose members of the operator family.

As an example, PostgreSQL has a built-in B-tree operator family `integer_ops`, which includes operator classes `int8_ops`, `int4_ops`, and `int2_ops` for indexes on `bigint`, `integer`, and `smallint` columns respectively. The family also contains cross-data-type comparison operators allowing any two of these types to be compared, so that an index on one of these types can be searched using a comparison value of another type. The family could be duplicated by these definitions:

```
CREATE OPERATOR FAMILY integer_ops USING btree;
CREATE OPERATOR CLASS int8_ops
DEFAULT FOR TYPE int8 USING btree FAMILY integer_ops AS
  -- standard int8 comparisons
  OPERATOR 1 < ,
  OPERATOR 2 <= ,
  OPERATOR 3 = ,
  OPERATOR 4 >= ,
  OPERATOR 5 > ,
  FUNCTION 1 btint8cmp(int8, int8) ;
CREATE OPERATOR CLASS int4_ops
DEFAULT FOR TYPE int4 USING btree FAMILY integer_ops AS
```
-- standard int4 comparisons
OPERATOR 1 <,
OPERATOR 2 <=,
OPERATOR 3 =,
OPERATOR 4 >=,
OPERATOR 5 >,
FUNCTION 1 btint4cmp(int4, int4);

CREATE OPERATOR CLASS int2_ops
DEFAULT FOR TYPE int2 USING btree FAMILY integer_ops AS
-- standard int2 comparisons
OPERATOR 1 <,
OPERATOR 2 <=,
OPERATOR 3 =,
OPERATOR 4 >=,
OPERATOR 5 >,
FUNCTION 1 btint2cmp(int2, int2);

ALTER OPERATOR FAMILY integer_ops USING btree ADD
-- cross-type comparisons int8 vs int2
OPERATOR 1 < (int8, int2),
OPERATOR 2 <= (int8, int2),
OPERATOR 3 = (int8, int2),
OPERATOR 4 >= (int8, int2),
OPERATOR 5 > (int8, int2),
FUNCTION 1 btint82cmp(int8, int2),

-- cross-type comparisons int8 vs int4
OPERATOR 1 < (int8, int4),
OPERATOR 2 <= (int8, int4),
OPERATOR 3 = (int8, int4),
OPERATOR 4 >= (int8, int4),
OPERATOR 5 > (int8, int4),
FUNCTION 1 btint84cmp(int8, int4),

-- cross-type comparisons int4 vs int2
OPERATOR 1 < (int4, int2),
OPERATOR 2 <= (int4, int2),
OPERATOR 3 = (int4, int2),
OPERATOR 4 >= (int4, int2),
OPERATOR 5 > (int4, int2),
FUNCTION 1 btint42cmp(int4, int2),

-- cross-type comparisons int4 vs int8
OPERATOR 1 < (int4, int8),
OPERATOR 2 <= (int4, int8),
OPERATOR 3 = (int4, int8),
OPERATOR 4 >= (int4, int8),
OPERATOR 5 > (int4, int8),
FUNCTION 1 btint48cmp(int4, int8),

-- cross-type comparisons int2 vs int8
OPERATOR 1 < (int2, int8),
OPERATOR 2 <= (int2, int8),
OPERATOR 3 = (int2, int8),
OPERATOR 4 >= (int2, int8),
OPERATOR 5 > (int2, int8),
FUNCTION 1 btint28cmp(int2, int8) ,
-- cross-type comparisons int2 vs int4
OPERATOR 1 < (int2, int4) ,
OPERATOR 2 <= (int2, int4) ,
OPERATOR 3 = (int2, int4) ,
OPERATOR 4 >= (int2, int4) ,
OPERATOR 5 > (int2, int4) ,
FUNCTION 1 btint24cmp(int2, int4) ;

Notice that this definition “overloads” the operator strategy and support function numbers: each number occurs multiple times within the family. This is allowed so long as each instance of a particular number has distinct input data types. The instances that have both input types equal to an operator class’s input type are the primary operators and support functions for that operator class, and in most cases should be declared as part of the operator class rather than as loose members of the family.

In a B-tree operator family, all the operators in the family must sort compatibly, meaning that the transitive laws hold across all the data types supported by the family: “if A = B and B = C, then A = C”, and “if A < B and B < C, then A < C”. For each operator in the family there must be a support function having the same two input data types as the operator. It is recommended that a family be complete, i.e., for each combination of data types, all operators are included. Each operator class should include just the non-cross-type operators and support function for its data type.

To build a multiple-data-type hash operator family, compatible hash support functions must be created for each data type supported by the family. Here compatibility means that the functions are guaranteed to return the same hash code for any two values that are considered equal by the family’s equality operators, even when the values are of different types. This is usually difficult to accomplish when the types have different physical representations, but it can be done in some cases. Notice that there is only one support function per data type, not one per equality operator. It is recommended that a family be complete, i.e., provide an equality operator for each combination of data types. Each operator class should include just the non-cross-type equality operator and the support function for its data type.

GIN and GiST indexes do not have any explicit notion of cross-data-type operations. The set of operators supported is just whatever the primary support functions for a given operator class can handle.

Note: Prior to PostgreSQL 8.3, there was no concept of operator families, and so any cross-data-type operators intended to be used with an index had to be bound directly into the index’s operator class. While this approach still works, it is deprecated because it makes an index’s dependencies too broad, and because the planner can handle cross-data-type comparisons more effectively when both data types have operators in the same operator family.

34.14.6. System Dependencies on Operator Classes

PostgreSQL uses operator classes to infer the properties of operators in more ways than just whether they can be used with indexes. Therefore, you might want to create operator classes even if you have no intention of indexing any columns of your data type.

In particular, there are SQL features such as ORDER BY and DISTINCT that require comparison and sorting of values. To implement these features on a user-defined data type, PostgreSQL looks for the default B-tree operator class for the data type. The “equals” member of this operator class defines the system’s notion of equality of values for GROUP BY and DISTINCT, and the sort ordering imposed by the operator class defines the default ORDER BY ordering.
Comparison of arrays of user-defined types also relies on the semantics defined by the default B-tree operator class.

If there is no default B-tree operator class for a data type, the system will look for a default hash operator class. But since that kind of operator class only provides equality, in practice it is only enough to support array equality.

When there is no default operator class for a data type, you will get errors like “could not identify an ordering operator” if you try to use these SQL features with the data type.

Note: In PostgreSQL versions before 7.4, sorting and grouping operations would implicitly use operators named =, <, and >. The new behavior of relying on default operator classes avoids having to make any assumption about the behavior of operators with particular names.

Another important point is that an operator that appears in a hash operator family is a candidate for hash joins, hash aggregation, and related optimizations. The hash operator family is essential here since it identifies the hash function(s) to use.

34.14.7. Special Features of Operator Classes

There are two special features of operator classes that we have not discussed yet, mainly because they are not useful with the most commonly used index methods.

Normally, declaring an operator as a member of an operator class (or family) means that the index method can retrieve exactly the set of rows that satisfy a WHERE condition using the operator. For example:

```
SELECT * FROM table WHERE integer_column < 4;
```

can be satisfied exactly by a B-tree index on the integer column. But there are cases where an index is useful as an inexact guide to the matching rows. For example, if a GiST index stores only bounding boxes for objects, then it cannot exactly satisfy a WHERE condition that tests overlap between non-rectangular objects such as polygons. Yet we could use the index to find objects whose bounding box overlaps the bounding box of the target object, and then do the exact overlap test only on the objects found by the index. If this scenario applies, the index is said to be “lossy” for the operator, and we add RECHECK to the OPERATOR clause in the CREATE OPERATOR CLASS command. RECHECK is valid if the index is guaranteed to return all the required rows, plus perhaps some additional rows, which can be eliminated by performing the original operator invocation.

Consider again the situation where we are storing in the index only the bounding box of a complex object such as a polygon. In this case there’s not much value in storing the whole polygon in the index entry — we might as well store just a simpler object of type box. This situation is expressed by the STORAGE option in CREATE OPERATOR CLASS: we’d write something like:

```
CREATE OPERATOR CLASS polygon_ops
    DEFAULT FOR TYPE polygon USING gist AS
    ...
    STORAGE box;
```

At present, only the GiST and GIN index methods support a STORAGE type that’s different from the column data type. The GiST compress and decompress support routines must deal with data-type conversion when STORAGE is used. In GIN, the STORAGE type identifies the type of the “key” values, which normally is different from the type of the indexed column — for example, an operator
class for integer-array columns might have keys that are just integers. The GIN extractValue and extractQuery support routines are responsible for extracting keys from indexed values.
Chapter 35. Triggers

This chapter provides general information about writing trigger functions. Trigger functions can be written in most of the available procedural languages, including PL/pgSQL (Chapter 38), PL/Tcl (Chapter 39), PL/Perl (Chapter 40), and PL/Python (Chapter 41). After reading this chapter, you should consult the chapter for your favorite procedural language to find out the language-specific details of writing a trigger in it.

It is also possible to write a trigger function in C, although most people find it easier to use one of the procedural languages. It is not currently possible to write a trigger function in the plain SQL function language.

35.1. Overview of Trigger Behavior

A trigger is a specification that the database should automatically execute a particular function whenever a certain type of operation is performed. Triggers can be defined to execute either before or after any INSERT, UPDATE, or DELETE operation, either once per modified row, or once per SQL statement. If a trigger event occurs, the trigger's function is called at the appropriate time to handle the event.

The trigger function must be defined before the trigger itself can be created. The trigger function must be declared as a function taking no arguments and returning type trigger. (The trigger function receives its input through a specially-passed TriggerData structure, not in the form of ordinary function arguments.)

Once a suitable trigger function has been created, the trigger is established with CREATE TRIGGER. The same trigger function can be used for multiple triggers.

PostgreSQL offers both per-row triggers and per-statement triggers. With a per-row trigger, the trigger function is invoked once for each row that is affected by the statement that fired the trigger. In contrast, a per-statement trigger is invoked only once when an appropriate statement is executed, regardless of the number of rows affected by that statement. In particular, a statement that affects zero rows will still result in the execution of any applicable per-statement triggers. These two types of triggers are sometimes called row-level triggers and statement-level triggers, respectively.

Triggers are also classified as before triggers and after triggers. Statement-level before triggers naturally fire before the statement starts to do anything, while statement-level after triggers fire at the very end of the statement. Row-level before triggers fire immediately before a particular row is operated on, while row-level after triggers fire at the end of the statement (but before any statement-level after triggers).

Trigger functions invoked by per-statement triggers should always return NULL. Trigger functions invoked by per-row triggers can return a table row (a value of type HeapTuple) to the calling executor, if they choose. A row-level trigger fired before an operation has the following choices:

- It can return NULL to skip the operation for the current row. This instructs the executor to not perform the row-level operation that invoked the trigger (the insertion or modification of a particular table row).
- For row-level INSERT and UPDATE triggers only, the returned row becomes the row that will be inserted or will replace the row being updated. This allows the trigger function to modify the row being inserted or updated.

A row-level before trigger that does not intend to cause either of these behaviors must be careful to return as its result the same row that was passed in (that is, the NEW row for INSERT and UPDATE
triggers, the OLD row for DELETE triggers).

The return value is ignored for row-level triggers fired after an operation, and so they can return NULL.

If more than one trigger is defined for the same event on the same relation, the triggers will be fired in alphabetical order by trigger name. In the case of before triggers, the possibly-modified row returned by each trigger becomes the input to the next trigger. If any before trigger returns NULL, the operation is abandoned for that row and subsequent triggers are not fired.

Typically, row before triggers are used for checking or modifying the data that will be inserted or updated. For example, a before trigger might be used to insert the current time into a timestamp column, or to check that two elements of the row are consistent. Row after triggers are most sensibly used to propagate the updates to other tables, or make consistency checks against other tables. The reason for this division of labor is that an after trigger can be certain it is seeing the final value of the row, while a before trigger cannot; there might be other before triggers firing after it. If you have no specific reason to make a trigger before or after, the before case is more efficient, since the information about the operation doesn’t have to be saved until end of statement.

If a trigger function executes SQL commands then these commands might fire triggers again. This is known as cascading triggers. There is no direct limitation on the number of cascade levels. It is possible for cascades to cause a recursive invocation of the same trigger; for example, an INSERT trigger might execute a command that inserts an additional row into the same table, causing the INSERT trigger to be fired again. It is the trigger programmer’s responsibility to avoid infinite recursion in such scenarios.

When a trigger is being defined, arguments can be specified for it. The purpose of including arguments in the trigger definition is to allow different triggers with similar requirements to call the same function. As an example, there could be a generalized trigger function that takes as its arguments two column names and puts the current user in one and the current time stamp in the other. Properly written, this trigger function would be independent of the specific table it is triggering on. So the same function could be used for INSERT events on any table with suitable columns, to automatically track creation of records in a transaction table for example. It could also be used to track last-update events if defined as an UPDATE trigger.

Each programming language that supports triggers has its own method for making the trigger input data available to the trigger function. This input data includes the type of trigger event (e.g., INSERT or UPDATE) as well as any arguments that were listed in CREATE TRIGGER. For a row-level trigger, the input data also includes the NEW row for INSERT and UPDATE triggers, and/or the OLD row for UPDATE and DELETE triggers. Statement-level triggers do not currently have any way to examine the individual row(s) modified by the statement.

### 35.2. Visibility of Data Changes

If you execute SQL commands in your trigger function, and these commands access the table that the trigger is for, then you need to be aware of the data visibility rules, because they determine whether these SQL commands will see the data change that the trigger is fired for. Briefly:

- Statement-level triggers follow simple visibility rules: none of the changes made by a statement are visible to statement-level triggers that are invoked before the statement, whereas all modifications are visible to statement-level after triggers.
- The data change (insertion, update, or deletion) causing the trigger to fire is naturally not visible to SQL commands executed in a row-level before trigger, because it hasn’t happened yet.
Chapter 35. Triggers

- However, SQL commands executed in a row-level before trigger will see the effects of data changes for rows previously processed in the same outer command. This requires caution, since the ordering of these change events is not in general predictable; a SQL command that affects multiple rows can visit the rows in any order.

- When a row-level after trigger is fired, all data changes made by the outer command are already complete, and are visible to the invoked trigger function.

Further information about data visibility rules can be found in Section 42.4. The example in Section 35.4 contains a demonstration of these rules.

35.3. Writing Trigger Functions in C

This section describes the low-level details of the interface to a trigger function. This information is only needed when writing trigger functions in C. If you are using a higher-level language then these details are handled for you. In most cases you should consider using a procedural language before writing your triggers in C. The documentation of each procedural language explains how to write a trigger in that language.

Trigger functions must use the “version 1” function manager interface.

When a function is called by the trigger manager, it is not passed any normal arguments, but it is passed a “context” pointer pointing to a `TriggerData` structure. C functions can check whether they were called from the trigger manager or not by executing the macro:

```
CALLED_AS_TRIGGER(fcinfo)
```

which expands to:

```
((fcinfo)->context != NULL && IsA((fcinfo)->context, TriggerData))
```

If this returns true, then it is safe to cast `fcinfo->context` to type `TriggerData *` and make use of the pointed-to `TriggerData` structure. The function must not alter the `TriggerData` structure or any of the data it points to.

`struct TriggerData` is defined in commands/trigger.h:

```
typedef struct TriggerData
{
    NodeTag     type;
    TriggerEvent tg_event;
    Relation     tg_relation;
    HeapTuple    tg_trigtuple;
    HeapTuple    tg_newtuple;
    Trigger     *tg_trigger;
    Buffer       tg_trigtuplebuf;
    Buffer       tg_newtuplebuf;
} TriggerData;
```

where the members are defined as follows:

```
type
    Always T_TriggerData.
```
Chapter 35. Triggers

tg_event
Describes the event for which the function is called. You can use the following macros to examine
tg_event:

TRIGGER_FIRED_BEFORE(tg_event)
Returns true if the trigger fired before the operation.

TRIGGER_FIRED_AFTER(tg_event)
Returns true if the trigger fired after the operation.

TRIGGER_FIRED_FOR_ROW(tg_event)
Returns true if the trigger fired for a row-level event.

TRIGGER_FIRED_FOR_STATEMENT(tg_event)
Returns true if the trigger fired for a statement-level event.

TRIGGER_FIRED_BY_INSERT(tg_event)
Returns true if the trigger was fired by an INSERT command.

TRIGGER_FIRED_BY_UPDATE(tg_event)
Returns true if the trigger was fired by an UPDATE command.

TRIGGER_FIRED_BY_DELETE(tg_event)
Returns true if the trigger was fired by a DELETE command.

tg_relation
A pointer to a structure describing the relation that the trigger fired for. Look at utils/rel.h for
details about this structure. The most interesting things are tg_relation->rd_att (descriptor
of the relation tuples) and tg_relation->rd_rel->relname (relation name; the type is not
char* but NameData; use SPI_getrelname(tg_relation) to get a char* if you need a
copy of the name).

tg_trigtuple
A pointer to the row for which the trigger was fired. This is the row being inserted, updated, or
deleted. If this trigger was fired for an INSERT or DELETE then this is what you should return
from the function if you don’t want to replace the row with a different one (in the case of INSERT)
or skip the operation.

tg_newtuple
A pointer to the new version of the row, if the trigger was fired for an UPDATE, and NULL if it is
for an INSERT or a DELETE. This is what you have to return from the function if the event is an
UPDATE and you don’t want to replace this row by a different one or skip the operation.

tg_trigger
A pointer to a structure of type Trigger, defined in utils/rel.h:
typedef struct Trigger
{
    Oid tgoeid;
    char *tgname;
    Oid tgfoid;
    int16 tgttype;
    char tgenabled;
};
Chapter 35. Triggers

bool tgisconstraint;
Oid tgconstrrelid;
Oid tgconstraint;
bool tgdeferrable;
bool tginitdeferred;
int16 tgnargs;
int16 tgnattr;
int16 *tgattr;
char **tgargs;
}

Trigger;

where tgname is the trigger’s name, tgnargs is number of arguments in tgargs, and tgargs is an array of pointers to the arguments specified in the CREATE TRIGGER statement. The other members are for internal use only.

tg_trigtuplebuf

The buffer containing tg_trigtuple, or InvalidBuffer if there is no such tuple or it is not stored in a disk buffer.

tg_newtuplebuf

The buffer containing tg_newtuple, or InvalidBuffer if there is no such tuple or it is not stored in a disk buffer.

A trigger function must return either a HeapTuple pointer or a NULL pointer (not an SQL null value, that is, do not set isNull true). Be careful to return either tg_trigtuple or tg_newtuple, as appropriate, if you don’t want to modify the row being operated on.

35.4. A Complete Example

Here is a very simple example of a trigger function written in C. (Examples of triggers written in procedural languages can be found in the documentation of the procedural languages.)

The function trigf reports the number of rows in the table ttest and skips the actual operation if the command attempts to insert a null value into the column x. (So the trigger acts as a not-null constraint but doesn’t abort the transaction.)

First, the table definition:

CREATE TABLE ttest (
    x integer
);

This is the source code of the trigger function:

#include "postgres.h"
#include "executor/spi.h" /* this is what you need to work with SPI */
#include "commands/trigger.h" /* ... and triggers */

extern Datum trigf(PG_FUNCTION_ARGS);

PG_FUNCTION_INFO_V1(trigf);

Datum
trigf(PG_FUNCTION_ARGS)
{
    TriggerData *trigdata = (TriggerData *) fcinfo->context;
    TupleDesc tupdesc;
    HeapTuple rettuple;
    char *when;
    bool checknull = false;
    bool isnull;
    int ret, i;

    /* make sure it's called as a trigger at all */
    if (!CALLED_AS_TRIGGER(fcinfo))
       elog(ERROR, "trigf: not called by trigger manager");

    /* tuple to return to executor */
    if (TRIGGER_FIRED_BY_UPDATE(trigdata->tg_event))
        rettuple = trigdata->tg_newtuple;
    else
        rettuple = trigdata->tg_trigtuple;

    /* check for null values */
    if (!TRIGGER_FIRED_BY_DELETE(trigdata->tg_event)
            && TRIGGER_FIRED_BEFORE(trigdata->tg_event))
        checknull = true;

    if (TRIGGER_FIRED_BEFORE(trigdata->tg_event))
        when = "before";
    else
        when = "after ";

    tupdesc = trigdata->tg_relation->rd_att;

    /* connect to SPI manager */
    if ((ret = SPI_connect()) < 0)
        elog(INFO, "trigf (fired %s): SPI_connect returned %d", when, ret);

    /* get number of rows in table */
    ret = SPI_exec("SELECT count(*) FROM ttest", 0);
    if (ret < 0)
        elog(NOTICE, "trigf (fired %s): SPI_exec returned %d", when, ret);

    /* count(*) returns int8, so be careful to convert */
    i = DatumGetInt64(SPI_getbinval(SPI_tuptable->vals[0],
                                   SPI_tuptable->tupdesc,
                                   1,
                                   &isnull));

    elog(INFO, "trigf (fired %s): there are %d rows in ttest", when, i);

    SPI_finish();

    if (checknull)
    {
        SPI_getbinval(rettuple, tupdesc, 1, &isnull);
        if (isnull)
            rettuple = NULL;
    }
After you have compiled the source code, declare the function and the triggers:

```sql
CREATE FUNCTION trigf() RETURNS trigger
AS 'filename'
LANGUAGE C;

CREATE TRIGGER tbefore BEFORE INSERT OR UPDATE OR DELETE ON ttest
FOR EACH ROW EXECUTE PROCEDURE trigf();

CREATE TRIGGER tafter AFTER INSERT OR UPDATE OR DELETE ON ttest
FOR EACH ROW EXECUTE PROCEDURE trigf();
```

Now you can test the operation of the trigger:

```sql
=> INSERT INTO ttest VALUES (NULL);
INFO: trigf (fired before): there are 0 rows in ttest
INSERT 0 0
-- Insertion skipped and AFTER trigger is not fired

=> SELECT * FROM ttest;
x
---
(0 rows)

=> INSERT INTO ttest VALUES (1);
INFO: trigf (fired before): there are 0 rows in ttest
INFO: trigf (fired after ): there are 1 rows in ttest

remember what we said about visibility.

INSERT 167793 1

vac= => SELECT * FROM ttest;
x
---
1
(1 row)

=> INSERT INTO ttest SELECT x * 2 FROM ttest;
INFO: trigf (fired before): there are 1 rows in ttest
INFO: trigf (fired after ): there are 2 rows in ttest

remember what we said about visibility.

INSERT 167794 1

=> SELECT * FROM ttest;
x
---
1
2
(2 rows)
```
Chapter 35. Triggers

=> UPDATE ttest SET x = NULL WHERE x = 2;
INFO: trigf (fired before): there are 2 rows in ttest
UPDATE 0
=> UPDATE ttest SET x = 4 WHERE x = 2;
INFO: trigf (fired before): there are 2 rows in ttest
INFO: trigf (fired after): there are 2 rows in ttest
UPDATE 1
vac=> SELECT * FROM ttest;
  x
---
  1
  4
(2 rows)

=> DELETE FROM ttest;
INFO: trigf (fired before): there are 2 rows in ttest
INFO: trigf (fired before): there are 1 rows in ttest
INFO: trigf (fired after): there are 0 rows in ttest
INFO: trigf (fired after): there are 0 rows in ttest

   ^^^^^^^

remember what we said about visibility.

DELETE 2
=> SELECT * FROM ttest;
  x
---
(0 rows)

There are more complex examples in src/test/regress/regress.c and in contrib/spi.
Chapter 36. The Rule System

This chapter discusses the rule system in PostgreSQL. Production rule systems are conceptually simple, but there are many subtle points involved in actually using them.

Some other database systems define active database rules, which are usually stored procedures and triggers. In PostgreSQL, these can be implemented using functions and triggers as well.

The rule system (more precisely speaking, the query rewrite rule system) is totally different from stored procedures and triggers. It modifies queries to take rules into consideration, and then passes the modified query to the query planner for planning and execution. It is very powerful, and can be used for many things such as query language procedures, views, and versions. The theoretical foundations and the power of this rule system are also discussed in *On Rules, Procedures, Caching and Views in Database Systems* and *A Unified Framework for Version Modeling Using Production Rules in a Database System*.

36.1. The Query Tree

To understand how the rule system works it is necessary to know when it is invoked and what its input and results are.

The rule system is located between the parser and the planner. It takes the output of the parser, one query tree, and the user-defined rewrite rules, which are also query trees with some extra information, and creates zero or more query trees as result. So its input and output are always things the parser itself could have produced and thus, anything it sees is basically representable as an SQL statement.

Now what is a query tree? It is an internal representation of an SQL statement where the single parts that it is built from are stored separately. These query trees can be shown in the server log if you set the configuration parameters `debug_print_parse`, `debug_print_rewritten`, or `debug_print_plan`. The rule actions are also stored as query trees, in the system catalog `pg_rewrite`. They are not formatted like the log output, but they contain exactly the same information.

Reading a raw query tree requires some experience. But since SQL representations of query trees are sufficient to understand the rule system, this chapter will not teach how to read them.

When reading the SQL representations of the query trees in this chapter it is necessary to be able to identify the parts the statement is broken into when it is in the query tree structure. The parts of a query tree are

the command type

This is a simple value telling which command (`SELECT`, `INSERT`, `UPDATE`, `DELETE`) produced the query tree.

the range table

The range table is a list of relations that are used in the query. In a `SELECT` statement these are the relations given after the `FROM` key word.

Every range table entry identifies a table or view and tells by which name it is called in the other parts of the query. In the query tree, the range table entries are referenced by number rather than by name, so here it doesn’t matter if there are duplicate names as it would in an SQL statement. This can happen after the range tables of rules have been merged in. The examples in this chapter will not have this situation.
Chapter 36. The Rule System

the result relation

This is an index into the range table that identifies the relation where the results of the query go.

SELECT queries normally don’t have a result relation. The special case of a SELECT INTO is mostly identical to a CREATE TABLE followed by a INSERT ... SELECT and is not discussed separately here.

For INSERT, UPDATE, and DELETE commands, the result relation is the table (or view!) where the changes are to take effect.

the target list

The target list is a list of expressions that define the result of the query. In the case of a SELECT, these expressions are the ones that build the final output of the query. They correspond to the expressions between the keywords SELECT and FROM. (* is just an abbreviation for all the column names of a relation. It is expanded by the parser into the individual columns, so the rule system never sees it.)

DELETE commands don’t need a target list because they don’t produce any result. In fact, the planner will add a special CTID entry to the empty target list, but this is after the rule system and will be discussed later; for the rule system, the target list is empty.

For INSERT commands, the target list describes the new rows that should go into the result relation. It consists of the expressions in the VALUES clause or the ones from the SELECT clause in INSERT ... SELECT. The first step of the rewrite process adds target list entries for any columns that were not assigned to by the original command but have defaults. Any remaining columns (with neither a given value nor a default) will be filled in by the planner with a constant null expression.

For UPDATE commands, the target list describes the new rows that should replace the old ones. In the rule system, it contains just the expressions from the SET column = expression part of the command. The planner will handle missing columns by inserting expressions that copy the values from the old row into the new one. And it will add the special CTID entry just as for DELETE, too.

Every entry in the target list contains an expression that can be a constant value, a variable pointing to a column of one of the relations in the range table, a parameter, or an expression tree made of function calls, constants, variables, operators, etc.

the qualification

The query’s qualification is an expression much like one of those contained in the target list entries. The result value of this expression is a Boolean that tells whether the operation (INSERT, UPDATE, DELETE, or SELECT) for the final result row should be executed or not. It corresponds to the WHERE clause of an SQL statement.

the join tree

The query’s join tree shows the structure of the FROM clause. For a simple query like SELECT ... FROM a, b, c the join tree is just a list of the FROM items, because we are allowed to join them in any order. But when JOIN expressions, particularly outer joins, are used, we have to join in the order shown by the joins. In that case, the join tree shows the structure of the JOIN expressions. The restrictions associated with particular JOIN clauses (from ON or USING expressions) are stored as qualification expressions attached to those join-tree nodes. It turns out to be convenient to store the top-level WHERE expression as a qualification attached to the top-level join-tree item, too. So really the join tree represents both the FROM and WHERE clauses of a SELECT.
Chapter 36. The Rule System

36.2. Views and the Rule System

Views in PostgreSQL are implemented using the rule system. In fact, there is essentially no difference between:

```
CREATE VIEW myview AS SELECT * FROM mytab;
```

compared against the two commands:

```
CREATE TABLE myview (same column list as mytab);
CREATE RULE "_RETURN" AS ON SELECT TO myview DO INSTEAD
    SELECT * FROM mytab;
```

because this is exactly what the `CREATE VIEW` command does internally. This has some side effects. One of them is that the information about a view in the PostgreSQL system catalogs is exactly the same as it is for a table. So for the parser, there is absolutely no difference between a table and a view. They are the same thing: relations.

36.2.1. How SELECT Rules Work

Rules `ON SELECT` are applied to all queries as the last step, even if the command given is an `INSERT`, `UPDATE` or `DELETE`. And they have different semantics from rules on the other command types in that they modify the query tree in place instead of creating a new one. So `SELECT` rules are described first.

Currently, there can be only one action in an `ON SELECT` rule, and it must be an unconditional `SELECT` action that is `INSTEAD`. This restriction was required to make rules safe enough to open them for ordinary users, and it restricts `ON SELECT` rules to act like views.

The examples for this chapter are two join views that do some calculations and some more views using them in turn. One of the two first views is customized later by adding rules for `INSERT`, `UPDATE`, and `DELETE` operations so that the final result will be a view that behaves like a real table with some magic functionality. This is not such a simple example to start from and this makes things harder to get into. But it’s better to have one example that covers all the points discussed step by step rather than having many different ones that might mix up in mind.

For the example, we need a little `min` function that returns the lower of 2 integer values. We create that as:

```
CREATE FUNCTION min(integer, integer) RETURNS integer AS $$
SELECT CASE WHEN $1 < $2 THEN $1 ELSE $2 END
$$ LANGUAGE SQL STRICT;
```

The real tables we need in the first two rule system descriptions are these:

```
CREATE TABLE shoe_data (  
    shoename    text, -- primary key
```
Chapter 36. The Rule System

sh_avail integer, -- available number of pairs
slcolor text, -- preferred shoelace color
slminlen real, -- minimum shoelace length
slmaxlen real, -- maximum shoelace length
slunit text -- length unit
);

CREATE TABLE shoelace_data {
  sl_name text, -- primary key
  sl_avail integer, -- available number of pairs
  sl_color text, -- shoelace color
  sl_len real, -- shoelace length
  sl_unit text -- length unit
};

CREATE TABLE unit {
  un_name text, -- primary key
  un_fact real -- factor to transform to cm
};

As you can see, they represent shoe-store data.

The views are created as:

CREATE VIEW shoe AS
SELECT sh.shoename,
  sh.sh_avail,
  sh.slcolor,
  sh.slminlen,
  sh.slminlen * un.un_fact AS slminlen_cm,
  sh.slmaxlen,
  sh.slmaxlen * un.un_fact AS slmaxlen_cm,
  sh.slunit
FROM shoe_data sh, unit un
WHERE sh.slunit = un.un_name;

CREATE VIEW shoelace AS
SELECT s.sl_name,
  s.sl_avail,
  s.sl_color,
  s.sl_len,
  s.sl_unit,
  s.sl_len * u.un_fact AS sl_len_cm
FROM shoelace_data s, unit u
WHERE s.sl_unit = u.un_name;

CREATE VIEW shoe_ready AS
SELECT rsh.shoename,
  rsh.sh_avail,
  rsl.sl_name,
  rsl.sl_avail,
  min(rsh.sh_avail, rsl.sl_avail) AS total_avail
FROM shoe rsh, shoelace rsl
WHERE rsl.sl_color = rsh.slcolor
AND rsl.sl_len_cm >= rsh.slminlen_cm
AND rsl.sl_len_cm <= rsh.slmaxlen_cm;
Chapter 36. The Rule System

The CREATE VIEW command for the shoelace view (which is the simplest one we have) will create a relation shoelace and an entry in pg_rewrite that tells that there is a rewrite rule that must be applied whenever the relation shoelace is referenced in a query’s range table. The rule has no rule qualification (discussed later, with the non-SELECT rules, since SELECT rules currently cannot have them) and it is INSTEAD. Note that rule qualifications are not the same as query qualifications. The action of our rule has a query qualification. The action of the rule is one query tree that is a copy of the SELECT statement in the view creation command.

**Note:** The two extra range table entries for NEW and OLD (named \*NEW* and \*OLD* for historical reasons in the printed query tree) you can see in the pg_rewrite entry aren’t of interest for SELECT rules.

Now we populate unit, shoe_data and shoelace_data and run a simple query on a view:

```sql
INSERT INTO unit VALUES ('cm', 1.0);
INSERT INTO unit VALUES ('m', 100.0);
INSERT INTO unit VALUES ('inch', 2.54);

INSERT INTO shoe_data VALUES ('sh1', 2, 'black', 70.0, 90.0, 'cm');
INSERT INTO shoe_data VALUES ('sh2', 0, 'black', 30.0, 40.0, 'inch');
INSERT INTO shoe_data VALUES ('sh3', 4, 'brown', 50.0, 65.0, 'cm');
INSERT INTO shoe_data VALUES ('sh4', 3, 'brown', 40.0, 50.0, 'inch');

INSERT INTO shoelace_data VALUES ('sl1', 5, 'black', 80.0, 'cm');
INSERT INTO shoelace_data VALUES ('sl2', 6, 'black', 100.0, 'cm');
INSERT INTO shoelace_data VALUES ('sl3', 0, 'black', 35.0, 'inch');
INSERT INTO shoelace_data VALUES ('sl4', 8, 'black', 40.0, 'inch');
INSERT INTO shoelace_data VALUES ('sl5', 4, 'brown', 1.0, 'm');
INSERT INTO shoelace_data VALUES ('sl6', 0, 'brown', 0.9, 'm');
INSERT INTO shoelace_data VALUES ('sl7', 7, 'brown', 60, 'cm');
INSERT INTO shoelace_data VALUES ('sl8', 1, 'brown', 40, 'inch');

SELECT * FROM shoelace;
```

### shoelace Output

<table>
<thead>
<tr>
<th>sl_name</th>
<th>sl_avail</th>
<th>sl_color</th>
<th>sl_len</th>
<th>sl_unit</th>
<th>sl_len_cm</th>
</tr>
</thead>
<tbody>
<tr>
<td>sl1</td>
<td>5</td>
<td>black</td>
<td>80</td>
<td>cm</td>
<td>80</td>
</tr>
<tr>

<td>35</td>
<td>inch</td>
<td>88.9</td>
</tr>
<tr>
<td>sl4</td>
<td>8</td>
<td>black</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl5</td>
<td>1</td>
<td>brown</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl6</td>
<td>0</td>
<td>brown</td>
<td>0.9</td>
<td>m</td>
<td>90</td>
</tr>
</tbody>
</table>

(8 rows)

This is the simplest SELECT you can do on our views, so we take this opportunity to explain the basics of view rules. The SELECT * FROM shoelace was interpreted by the parser and produced the query tree:

```sql
SELECT shoelace.sl_name, shoelace.sl_avail,
       shoelace.sl_color, shoelace.sl_len,
       shoelace.sl_unit, shoelace.sl_len_cm
FROM shoelace;
```
FROM shoelace shoelace;

and this is given to the rule system. The rule system walks through the range table and checks if there are rules for any relation. When processing the range table entry for shoelace (the only one up to now) it finds the _RETURN_ rule with the query tree:

```
SELECT s.sl_name, s.sl_avail, s.sl_color, s.sl_len, s.sl_unit, s.sl_len * u.un_fact AS sl_len_cm
FROM shoelace *OLD*, shoelace *NEW*, shoelace_data s, unit u
WHERE s.sl_unit = u.un_name;
```

To expand the view, the rewriter simply creates a subquery range-table entry containing the rule’s action query tree, and substitutes this range table entry for the original one that referenced the view. The resulting rewritten query tree is almost the same as if you had typed:

```
SELECT shoelace.sl_name, shoelace.sl_avail, shoelace.sl_color, shoelace.sl_len, shoelace.sl_unit, shoelace.sl_len_cm
FROM (SELECT s.sl_name, s.sl_avail, s.sl_color, s.sl_len, s.sl_unit, s.sl_len * u.un_fact AS sl_len_cm
FROM shoelace_data s, unit u
WHERE s.sl_unit = u.un_name) shoelace;
```

There is one difference however: the subquery’s range table has two extra entries shoelace *OLD* and shoelace *NEW*. These entries don’t participate directly in the query, since they aren’t referenced by the subquery’s join tree or target list. The rewriter uses them to store the access privilege check information that was originally present in the range-table entry that referenced the view. In this way, the executor will still check that the user has proper privileges to access the view, even though there’s no direct use of the view in the rewritten query.

That was the first rule applied. The rule system will continue checking the remaining range-table entries in the top query (in this example there are no more), and it will recursively check the range-table entries in the added subquery to see if any of them reference views. (But it won’t expand *OLD* or *NEW* — otherwise we’d have infinite recursion!) In this example, there are no rewrite rules for shoelace_data or unit, so rewriting is complete and the above is the final result given to the planner.

Now we want to write a query that finds out for which shoes currently in the store we have the matching shoelaces (color and length) and where the total number of exactly matching pairs is greater or equal to two.

```
SELECT * FROM shoe_ready WHERE total_avail >= 2;
```

<table>
<thead>
<tr>
<th>shoename</th>
<th>sh_avail</th>
<th>sl_name</th>
<th>sl_avail</th>
<th>total_avail</th>
</tr>
</thead>
<tbody>
<tr>

Chapter 36. The Rule System

The output of the parser this time is the query tree:

```sql
SELECT shoe_ready.shoename, shoe_ready.sh_avail,
       shoe_ready.sl_name, shoe_ready.sl_avail,
       shoe_ready.total_avail
FROM shoe_ready shoe_ready
WHERE shoe_ready.total_avail >= 2;
```

The first rule applied will be the one for the `shoe_ready` view and it results in the query tree:

```sql
SELECT shoe_ready.shoename, shoe_ready.sh_avail,
       shoe_ready.sl_name, shoe_ready.sl_avail,
       shoe_ready.total_avail
FROM (SELECT rsh.shoename,
           rsh.sh_avail,
           rsl.sl_name,
           rsl.sl_avail,
           min(rsh.sh_avail, rsl.sl_avail) AS total_avail
    FROM shoe rsh, shoelace rsl
    WHERE rsl.sl_color = rsh.slcolor
    AND rsl.sl_len_cm >= rsh.slminlen_cm
    AND rsl.sl_len_cm <= rsh.slmaxlen_cm) shoe_ready
WHERE shoe_ready.total_avail >= 2;
```

Similarly, the rules for `shoe` and `shoelace` are substituted into the range table of the subquery, leading to a three-level final query tree:

```sql
SELECT shoe_ready.shoename, shoe_ready.sh_avail,
       shoe_ready.sl_name, shoe_ready.sl_avail,
       shoe_ready.total_avail
FROM (SELECT rsh.shoename,
           rsh.sh_avail,
           rsl.sl_name,
           rsl.sl_avail,
           min(rsh.sh_avail, rsl.sl_avail) AS total_avail
    FROM (SELECT sh.shoename,
             sh.sh_avail,
             sh.slcolor,
             sh.slminlen,
             sh.slminlen * un.un_fact AS slminlen_cm,
             sh.slmaxlen,
             sh.slmaxlen * un.un_fact AS slmaxlen_cm,
             sh.slunit
        FROM shoe_data sh, unit un
        WHERE sh.slunit = un.un_name) rsh,
        (SELECT s.sl_name,
             s.sl_avail,
             s.sl_color,
             s.sl_len,
             s.sl_unit,
             s.sl_len * u.un_fact AS sl_len_cm
        FROM shoelace_data s, unit u
        WHERE s.sl_unit = u.un_name) rsl
    WHERE rsl.sl_color = rsh.slcolor
    AND rsl.sl_len_cm >= rsh.slminlen_cm
    AND rsl.sl_len_cm <= rsh.slmaxlen_cm) shoe_ready
```
WHERE shoe_ready.total_avail > 2;

It turns out that the planner will collapse this tree into a two-level query tree: the bottommost \texttt{SELECT} commands will be “pulled up” into the middle \texttt{SELECT} since there’s no need to process them separately. But the middle \texttt{SELECT} will remain separate from the top, because it contains aggregate functions. If we pulled those up it would change the behavior of the topmost \texttt{SELECT}, which we don’t want. However, collapsing the query tree is an optimization that the rewrite system doesn’t have to concern itself with.

### 36.2.2. View Rules in Non-\texttt{SELECT} Statements

Two details of the query tree aren’t touched in the description of view rules above. These are the command type and the result relation. In fact, view rules don’t need this information.

There are only a few differences between a query tree for a \texttt{SELECT} and one for any other command. Obviously, they have a different command type and for a command other than a \texttt{SELECT}, the result relation points to the range-table entry where the result should go. Everything else is absolutely the same. So having two tables \texttt{t1} and \texttt{t2} with columns \texttt{a} and \texttt{b}, the query trees for the two statements:

\begin{verbatim}
SELECT t2.b FROM t1, t2 WHERE t1.a = t2.a;
UPDATE t1 SET b = t2.b FROM t2 WHERE t1.a = t2.a;
\end{verbatim}

are nearly identical. In particular:

- The range tables contain entries for the tables \texttt{t1} and \texttt{t2}.
- The target lists contain one variable that points to column \texttt{b} of the range table entry for table \texttt{t2}.
- The qualification expressions compare the columns \texttt{a} of both range-table entries for equality.
- The join trees show a simple join between \texttt{t1} and \texttt{t2}.

The consequence is, that both query trees result in similar execution plans: They are both joins over the two tables. For the \texttt{UPDATE} the missing columns from \texttt{t1} are added to the target list by the planner and the final query tree will read as:

\begin{verbatim}
UPDATE t1 SET a = t1.a, b = t2.b FROM t2 WHERE t1.a = t2.a;
\end{verbatim}

and thus the executor run over the join will produce exactly the same result set as a:

\begin{verbatim}
SELECT t1.a, t2.b FROM t1, t2 WHERE t1.a = t2.a;
\end{verbatim}

will do. But there is a little problem in \texttt{UPDATE}: The executor does not care what the results from the join it is doing are meant for. It just produces a result set of rows. The difference that one is a \texttt{SELECT} command and the other is an \texttt{UPDATE} is handled in the caller of the executor. The caller still knows (looking at the query tree) that this is an \texttt{UPDATE}, and it knows that this result should go into table \texttt{t1}. But which of the rows that are there has to be replaced by the new row?

To resolve this problem, another entry is added to the target list in \texttt{UPDATE} (and also in \texttt{DELETE}) statements: the current tuple ID (CTID). This is a system column containing the file block number...
and position in the block for the row. Knowing the table, the CTID can be used to retrieve the original row of \( t_1 \) to be updated. After adding the CTID to the target list, the query actually looks like:

\[
\text{SELECT } t1.a, t2.b, t1.ctid \text{ FROM } t1, t2 \text{ WHERE } t1.a = t2.a;
\]

Now another detail of PostgreSQL enters the stage. Old table rows aren’t overwritten, and this is why \texttt{ROLLBACK} is fast. In an \texttt{UPDATE}, the new result row is inserted into the table (after stripping the CTID) and in the row header of the old row, which the CTID pointed to, the \( \text{cmax} \) and \( \text{xmax} \) entries are set to the current command counter and current transaction ID. Thus the old row is hidden, and after the transaction commits the vacuum cleaner can really remove it.

Knowing all that, we can simply apply view rules in absolutely the same way to any command. There is no difference.

### 36.2.3. The Power of Views in PostgreSQL

The above demonstrates how the rule system incorporates view definitions into the original query tree. In the second example, a simple \texttt{SELECT} from one view created a final query tree that is a join of 4 tables (\texttt{unit} was used twice with different names).

The benefit of implementing views with the rule system is, that the planner has all the information about which tables have to be scanned plus the relationships between these tables plus the restrictive qualifications from the views plus the qualifications from the original query in one single query tree. And this is still the situation when the original query is already a join over views. The planner has to decide which is the best path to execute the query, and the more information the planner has, the better this decision can be. And the rule system as implemented in PostgreSQL ensures, that this is all information available about the query up to that point.

### 36.2.4. Updating a View

What happens if a view is named as the target relation for an \texttt{INSERT}, \texttt{UPDATE}, or \texttt{DELETE}? After doing the substitutions described above, we will have a query tree in which the result relation points at a subquery range-table entry. This will not work, so the rewriter throws an error if it sees it has produced such a thing.

To change this, we can define rules that modify the behavior of these kinds of commands. This is the topic of the next section.

### 36.3. Rules on \texttt{INSERT}, \texttt{UPDATE}, and \texttt{DELETE}

Rules that are defined on \texttt{INSERT}, \texttt{UPDATE}, and \texttt{DELETE} are significantly different from the view rules described in the previous section. First, their \texttt{CREATE RULE} command allows more:

- They are allowed to have no action.
- They can have multiple actions.
- They can be \texttt{INSTEAD} or \texttt{ALSO} (the default).
- The pseudorelations \texttt{NEW} and \texttt{OLD} become useful.
• They can have rule qualifications.

Second, they don’t modify the query tree in place. Instead they create zero or more new query trees and can throw away the original one.

### 36.3.1. How Update Rules Work

Keep the syntax:

```sql
CREATE [ OR REPLACE ] RULE name AS ON event
    TO table [ WHERE condition ]
    DO [ ALSO | INSTEAD ] { NOTHING | command | { command ; command ... } }
```

in mind. In the following, update rules means rules that are defined on `INSERT`, `UPDATE`, or `DELETE`. Update rules get applied by the rule system when the result relation and the command type of a query tree are equal to the object and event given in the `CREATE RULE` command. For update rules, the rule system creates a list of query trees. Initially the query-tree list is empty. There can be zero (`NOTHING` key word), one, or multiple actions. To simplify, we will look at a rule with one action. This rule can have a qualification or not and it can be `INSTEAD` or `ALSO` (the default).

What is a rule qualification? It is a restriction that tells when the actions of the rule should be done and when not. This qualification can only reference the pseudorelations `NEW` and/or `OLD`, which basically represent the relation that was given as object (but with a special meaning).

So we have three cases that produce the following query trees for a one-action rule.

**No qualification, with either `ALSO` or `INSTEAD`**

the query tree from the rule action with the original query tree’s qualification added

**Qualification given and `ALSO`**

the query tree from the rule action with the rule qualification and the original query tree’s qualification added

**Qualification given and `INSTEAD`**

the query tree from the rule action with the rule qualification and the original query tree’s qualification; and the original query tree with the negated rule qualification added

Finally, if the rule is `ALSO`, the unchanged original query tree is added to the list. Since only qualified `INSTEAD` rules already add the original query tree, we end up with either one or two output query trees for a rule with one action.

For `ON INSERT` rules, the original query (if not suppressed by `INSTEAD`) is done before any actions added by rules. This allows the actions to see the inserted row(s). But for `ON UPDATE` and `ON DELETE` rules, the original query is done after the actions added by rules. This ensures that the actions can see the to-be-updated or to-be-deleted rows; otherwise, the actions might do nothing because they find no rows matching their qualifications.

The query trees generated from rule actions are thrown into the rewrite system again, and maybe more rules get applied resulting in more or less query trees. So a rule’s actions must have either a different command type or a different result relation than the rule itself is on, otherwise this recursive process will end up in an infinite loop. (Recursive expansion of a rule will be detected and reported as an error.)

The query trees found in the actions of the `pg_rewrite` system catalog are only templates. Since they can reference the range-table entries for `NEW` and `OLD`, some substitutions have to be made before they can be used. For any reference to `NEW`, the target list of the original query is searched for a
corresponding entry. If found, that entry’s expression replaces the reference. Otherwise, NEW means the same as OLD (for an UPDATE) or is replaced by a null value (for an INSERT). Any reference to OLD is replaced by a reference to the range-table entry that is the result relation.

After the system is done applying update rules, it applies view rules to the produced query tree(s). Views cannot insert new update actions so there is no need to apply update rules to the output of view rewriting.

### 36.3.1.1. A First Rule Step by Step

Say we want to trace changes to the sl_avail column in the shoelace_data relation. So we set up a log table and a rule that conditionally writes a log entry when an UPDATE is performed on shoelace_data.

```sql
CREATE TABLE shoelace_log {
    sl_name text, -- shoelace changed
    sl_avail integer, -- new available value
    log_who text, -- who did it
    log_when timestamp -- when
};

CREATE RULE log_shoelace AS ON UPDATE TO shoelace_data
WHERE NEW.sl_avail <> OLD.sl_avail
DO INSERT INTO shoelace_log VALUES (
    NEW.sl_name,
    NEW.sl_avail,
    current_user,
    current_timestamp
);
```

Now someone does:

```sql
UPDATE shoelace_data SET sl_avail = 6 WHERE sl_name = 'sl7';
```

and we look at the log table:

```sql
SELECT * FROM shoelace_log;
```

<table>
<thead>
<tr>
<th>sl_name</th>
<th>sl_avail</th>
<th>log_who</th>
<th>log_when</th>
</tr>
</thead>
<tbody>
<tr>
<td>sl7</td>
<td>6</td>
<td>A1</td>
<td>Tue Oct 20 16:14:45 1998 MET DST</td>
</tr>
</tbody>
</table>

(1 row)

That’s what we expected. What happened in the background is the following. The parser created the query tree:

```sql
UPDATE shoelace_data SET sl_avail = 6
FROM shoelace_data shoelace_data
WHERE shoelace_data.sl_name = 'sl7';
```

There is a rule log_shoelace that is ON UPDATE with the rule qualification expression:

```sql
NEW.sl_avail <> OLD.sl_avail
```
and the action:

```
INSERT INTO shoelace_log VALUES (
  *NEW*.sl_name, *NEW*.sl_avail,
  current_user, current_timestamp )
FROM shoelace_data *NEW*, shoelace_data *OLD*;
```

(This looks a little strange since you cannot normally write `INSERT ... VALUES ... FROM`. The `FROM` clause here is just to indicate that there are range-table entries in the query tree for *NEW* and *OLD*. These are needed so that they can be referenced by variables in the `INSERT` command’s query tree.)

The rule is a qualified `ALSO` rule, so the rule system has to return two query trees: the modified rule action and the original query tree. In step 1, the range table of the original query is incorporated into the rule’s action query tree. This results in:

```
INSERT INTO shoelace_log VALUES (
  *NEW*.sl_name, *NEW*.sl_avail,
  current_user, current_timestamp )
FROM shoelace_data *NEW*, shoelace_data *OLD*,
  shoelace_data shoelace_data;
```

In step 2, the rule qualification is added to it, so the result set is restricted to rows where `sl_avail` changes:

```
INSERT INTO shoelace_log VALUES (
  *NEW*.sl_name, *NEW*.sl_avail,
  current_user, current_timestamp )
FROM shoelace_data *NEW*, shoelace_data *OLD*,
  shoelace_data shoelace_data
WHERE *NEW*.sl_avail <> *OLD*.sl_avail;
```

(This looks even stranger, since `INSERT ... VALUES` doesn’t have a `WHERE` clause either, but the planner and executor will have no difficulty with it. They need to support this same functionality anyway for `INSERT ... SELECT`.)

In step 3, the original query tree’s qualification is added, restricting the result set further to only the rows that would have been touched by the original query:

```
INSERT INTO shoelace_log VALUES (
  *NEW*.sl_name, *NEW*.sl_avail,
  current_user, current_timestamp )
FROM shoelace_data *NEW*, shoelace_data *OLD*,
  shoelace_data shoelace_data
WHERE *NEW*.sl_avail <> *OLD*.sl_avail
  AND shoelace_data.sl_name = 'sl7';
```

Step 4 replaces references to `NEW` by the target list entries from the original query tree or by the matching variable references from the result relation:

```
INSERT INTO shoelace_log VALUES ( 
  shoelace_data.sl_name, 6,
  current_user, current_timestamp )
FROM shoelace_data *NEW*, shoelace_data *OLD*,
  shoelace_data shoelace_data
WHERE 6 <> *OLD*.sl_avail
```
AND shoelace_data.sl_name = 'sl7';

Step 5 changes OLD references into result relation references:

```
INSERT INTO shoelace_log VALUES (
    shoelace_data.sl_name, 6,
    current_user, current_timestamp )
FROM shoelace_data *NEW*, shoelace_data *OLD*,
shoelace_data shoelace_data
WHERE 6 <> shoelace_data.sl_avail
    AND shoelace_data.sl_name = 'sl7';
```

That’s it. Since the rule is ALSO, we also output the original query tree. In short, the output from the rule system is a list of two query trees that correspond to these statements:

```
INSERT INTO shoelace_log VALUES (
    shoelace_data.sl_name, 6,
    current_user, current_timestamp )
FROM shoelace_data
WHERE 6 <> shoelace_data.sl_avail
    AND shoelace_data.sl_name = 'sl7';

UPDATE shoelace_data SET sl_avail = 6
WHERE sl_name = 'sl7';
```

These are executed in this order, and that is exactly what the rule was meant to do.

The substitutions and the added qualifications ensure that, if the original query would be, say:

```
UPDATE shoelace_data SET sl_color = 'green'
WHERE sl_name = 'sl7';
```

no log entry would get written. In that case, the original query tree does not contain a target list entry for sl_avail, so NEW.sl_avail will get replaced by shoelace_data.si_avail. Thus, the extra command generated by the rule is:

```
INSERT INTO shoelace_log VALUES (
    shoelace_data.sl_name, shoelace_data.sl_avail,
    current_user, current_timestamp )
FROM shoelace_data
WHERE shoelace_data.sl_avail <> shoelace_data.sl_avail
    AND shoelace_data.sl_name = 'sl7';
```

and that qualification will never be true.

It will also work if the original query modifies multiple rows. So if someone issued the command:

```
UPDATE shoelace_data SET sl_avail = 0
WHERE sl_color = 'black';
```

four rows in fact get updated (sl1, sl2, sl3, and sl4). But sl3 already has sl_avail = 0. In this case, the original query trees qualification is different and that results in the extra query tree:

```
INSERT INTO shoelace_log
SELECT shoelace_data.sl_name, 0,
    current_user, current_timestamp
FROM shoelace_data
WHERE shoelace_data.sl_name = 'sl7';
```
FROM shoelace_data
WHERE 0 <> shoelace_data.sl_avail
AND shoelace_data.sl_color = 'black';

being generated by the rule. This query tree will surely insert three new log entries. And that’s absolutely correct.

Here we can see why it is important that the original query tree is executed last. If the UPDATE had been executed first, all the rows would have already been set to zero, so the logging INSERT would not find any row where 0 <> shoelace_data.sl_avail.

### 36.3.2. Cooperation with Views

A simple way to protect view relations from the mentioned possibility that someone can try to run INSERT, UPDATE, or DELETE on them is to let those query trees get thrown away. So we could create the rules:

CREATE RULE shoe_ins_protect AS ON INSERT TO shoe
  DO INSTEAD NOTHING;
CREATE RULE shoe_upd_protect AS ON UPDATE TO shoe
  DO INSTEAD NOTHING;
CREATE RULE shoe_del_protect AS ON DELETE TO shoe
  DO INSTEAD NOTHING;

If someone now tries to do any of these operations on the view relation shoe, the rule system will apply these rules. Since the rules have no actions and are INSTEAD, the resulting list of query trees will be empty and the whole query will become nothing because there is nothing left to be optimized or executed after the rule system is done with it.

A more sophisticated way to use the rule system is to create rules that rewrite the query tree into one that does the right operation on the real tables. To do that on the shoelace view, we create the following rules:

CREATE RULE shoelace_ins AS ON INSERT TO shoelace
  DO INSTEAD
    INSERT INTO shoelace_data VALUES ( NEW.sl_name, 
                                          NEW.sl_avail, 
                                          NEW.sl_color, 
                                          NEW.sl_len, 
                                          NEW.sl_unit );

CREATE RULE shoelace_upd AS ON UPDATE TO shoelace
  DO INSTEAD
    UPDATE shoelace_data
      SET sl_name = NEW.sl_name, 
          sl_avail = NEW.sl_avail, 
          sl_color = NEW.sl_color, 
          sl_len = NEW.sl_len, 
          sl_unit = NEW.sl_unit 
      WHERE sl_name = OLD.sl_name;

CREATE RULE shoelace_del AS ON DELETE TO shoelace
  DO INSTEAD
DELETE FROM shoelace_data
WHERE sl_name = OLD.sl_name;

If you want to support RETURNING queries on the view, you need to make the rules include
RETURNING clauses that compute the view rows. This is usually pretty trivial for views on a single
table, but it’s a bit tedious for join views such as shoelace. An example for the insert case is:

CREATE RULE shoelace_ins AS ON INSERT TO shoelace
DO INSTEAD
  INSERT INTO shoelace_data VALUES (
    NEW.sl_name,
    NEW.sl_avail,
    NEW.sl_color,
    NEW.sl_len,
    NEW.sl_unit
  )
RETURNING
  shoelace_data.*,
  (SELECT shoelace_data.sl_len * u.un_fact
   FROM unit u WHERE shoelace_data.sl_unit = u.un_name);

Note that this one rule supports both INSERT and INSERT RETURNING queries on the view — the
RETURNING clause is simply ignored for INSERT.

Now assume that once in a while, a pack of shoelaces arrives at the shop and a big parts list along
with it. But you don’t want to manually update the shoelace view every time. Instead we setup two
little tables: one where you can insert the items from the part list, and one with a special trick. The
creation commands for these are:

CREATE TABLE shoelace_arrive (  
  arr_name  text,
  arr_quant integer
);

CREATE TABLE shoelace_ok (  
  ok_name  text,
  ok_quant integer
);

CREATE RULE shoelace_ok_ins AS ON INSERT TO shoelace_ok
DO INSTEAD
  UPDATE shoelace
  SET sl_avail = sl_avail + NEW.ok_quant
  WHERE sl_name = NEW.ok_name;

Now you can fill the table shoelace_arrive with the data from the parts list:

SELECT * FROM shoelace_arrive;

arr_name | arr_quant
----------+----------
sl3       | 10       
sl6       | 20       
sl8       | 20       
(3 rows)
Take a quick look at the current data:

```
SELECT * FROM shoelace;
```

<table>
<thead>
<tr>
<th>sl_name</th>
<th>sl_avail</th>
<th>sl_color</th>
<th>sl_len</th>
<th>sl_unit</th>
<th>sl_len_cm</th>
</tr>
</thead>
<tbody>
<tr>
<td>sl1</td>
<td>5</td>
<td>black</td>
<td>80</td>
<td>cm</td>
<td>80</td>
</tr>
<tr>
<td>sl2</td>
<td>6</td>
<td>black</td>
<td>100</td>
<td>cm</td>
<td>100</td>
</tr>
<tr>
<td>sl7</td>
<td>6</td>
<td>brown</td>
<td>60</td>
<td>cm</td>
<td>60</td>
</tr>
<tr>
<td>sl3</td>
<td>0</td>
<td>black</td>
<td>35</td>
<td>inch</td>
<td>88.9</td>
</tr>
<tr>
<td>sl4</td>
<td>8</td>
<td>black</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl8</td>
<td>1</td>
<td>brown</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl5</td>
<td>4</td>
<td>brown</td>
<td>1</td>
<td>m</td>
<td>100</td>
</tr>
<tr>
<td>sl6</td>
<td>0</td>
<td>brown</td>
<td>0.9</td>
<td>m</td>
<td>90</td>
</tr>
</tbody>
</table>

(8 rows)

Now move the arrived shoelaces in:

```
INSERT INTO shoelace_ok SELECT * FROM shoelace_arrive;
```

and check the results:

```
SELECT * FROM shoelace ORDER BY sl_name;
```

<table>
<thead>
<tr>
<th>sl_name</th>
<th>sl_avail</th>
<th>sl_color</th>
<th>sl_len</th>
<th>sl_unit</th>
<th>sl_len_cm</th>
</tr>
</thead>
<tbody>
<tr>
<td>sl1</td>
<td>5</td>
<td>black</td>
<td>80</td>
<td>cm</td>
<td>80</td>
</tr>
<tr>
<td>sl2</td>
<td>6</td>
<td>black</td>
<td>100</td>
<td>cm</td>
<td>100</td>
</tr>
<tr>
<td>sl7</td>
<td>6</td>
<td>brown</td>
<td>60</td>
<td>cm</td>
<td>60</td>
</tr>
<tr>
<td>sl4</td>
<td>8</td>
<td>black</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl3</td>
<td>10</td>
<td>black</td>
<td>35</td>
<td>inch</td>
<td>88.9</td>
</tr>
<tr>
<td>sl8</td>
<td>21</td>
<td>brown</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl5</td>
<td>4</td>
<td>brown</td>
<td>1</td>
<td>m</td>
<td>100</td>
</tr>
<tr>
<td>sl6</td>
<td>20</td>
<td>brown</td>
<td>0.9</td>
<td>m</td>
<td>90</td>
</tr>
</tbody>
</table>

(8 rows)

```
SELECT * FROM shoelace_log;
```

<table>
<thead>
<tr>
<th>sl_name</th>
<th>sl_avail</th>
<th>log_who</th>
<th>log_when</th>
</tr>
</thead>
<tbody>
<tr>
<td>sl7</td>
<td>6</td>
<td>Al</td>
<td>Tue Oct 20 19:14:45 1998 MET DST</td>
</tr>
<tr>
<td>sl3</td>
<td>10</td>
<td>Al</td>
<td>Tue Oct 20 19:25:16 1998 MET DST</td>
</tr>
<tr>
<td>sl6</td>
<td>20</td>
<td>Al</td>
<td>Tue Oct 20 19:25:16 1998 MET DST</td>
</tr>
<tr>
<td>sl8</td>
<td>21</td>
<td>Al</td>
<td>Tue Oct 20 19:25:16 1998 MET DST</td>
</tr>
</tbody>
</table>

(4 rows)

It’s a long way from the one INSERT ... SELECT to these results. And the description of the query-tree transformation will be the last in this chapter. First, there is the parser’s output:

```
INSERT INTO shoelace_ok
SELECT shoelace_arrive.arr_name, shoelace_arrive.arr_quant
    FROM shoelace_arrive, shoelace_ok;
```

Now the first rule shoelace_ok_ins is applied and turns this into:

```
UPDATE shoelace
```
SET sl_avail = shoelace.sl_avail + shoelace_arrive.arr_quant
FROM shoelace_arrive shoelace_arrive, shoelace_ok shoelace_ok,
    shoelace_ok *OLD*, shoelace_ok *NEW*,
shoelace shoelace
WHERE shoelace.sl_name = shoelace_arrive.arr_name;

and throws away the original INSERT on shoelace_ok. This rewritten query is passed to the rule system again, and the second applied rule shoelace_upd produces:

UPDATE shoelace_data
SET sl_name = shoelace.sl_name,
    sl_avail = shoelace.sl_avail + shoelace_arrive.arr_quant,
    sl_color = shoelace.sl_color,
    sl_len = shoelace.sl_len,
    sl_unit = shoelace.sl_unit
FROM shoelace_arrive shoelace_arrive, shoelace_ok shoelace_ok,
    shoelace_ok *OLD*, shoelace_ok *NEW*,
shoelace shoelace, shoelace *OLD*,
shoelace *NEW*, shoelace_data shoelace_data
WHERE shoelace.sl_name = shoelace_arrive.arr_name
    AND shoelace_data.sl_name = shoelace.sl_name;

Again it’s an INSTEAD rule and the previous query tree is trashed. Note that this query still uses the view shoelace. But the rule system isn’t finished with this step, so it continues and applies the _RETURN rule on it, and we get:

UPDATE shoelace_data
SET sl_name = s.sl_name,
    sl_avail = s.sl_avail + shoelace_arrive.arr_quant,
    sl_color = s.sl_color,
    sl_len = s.sl_len,
    sl_unit = s.sl_unit
FROM shoelace_arrive shoelace_arrive, shoelace_ok shoelace_ok,
    shoelace_ok *OLD*, shoelace_ok *NEW*,
shoelace shoelace, shoelace *OLD*,
shoelace *NEW*, shoelace_data shoelace_data,
shoelace_data s, unit u
WHERE s.sl_name = shoelace_arrive.arr_name
    AND shoelace_data.sl_name = s.sl_name;

Finally, the rule log_shoelace gets applied, producing the extra query tree:

INSERT INTO shoelace_log
SELECT s.sl_name,
    s.sl_avail + shoelace_arrive.arr_quant,
    current_user,
    current_timestamp
FROM shoelace_arrive shoelace_arrive, shoelace_ok shoelace_ok,
    shoelace_ok *OLD*, shoelace_ok *NEW*,
shoelace shoelace, shoelace *OLD*,
shoelace *NEW*, shoelace_data shoelace_data,
shoelace *OLD*, shoelace *NEW*,
shoelace_data s, unit u,
shoelace_data *OLD*, shoelace_data *NEW*
shoelace_log shoelace_log
WHERE s.sl_name = shoelace_arrive.arr_name
AND shoelace_data.sl_name = s.sl_name
AND (s.sl_avail + shoelace_arrive.arr_quant) <> s.sl_avail;

After that the rule system runs out of rules and returns the generated query trees.
So we end up with two final query trees that are equivalent to the SQL statements:

```
INSERT INTO shoelace_log
SELECT s.sl_name,
     s.sl_avail + shoelace_arrive.arr_quant,
     current_user,
     current_timestamp
FROM shoelace_arrive shoelace_arrive, shoelace_data shoelace_data,
     shoelace_data s
WHERE s.sl_name = shoelace_arrive.arr_name
AND shoelace_data.sl_name = s.sl_name
AND s.sl_avail + shoelace_arrive.arr_quant <> s.sl_avail;
```

```
UPDATE shoelace_data
SET sl_avail = shoelace_data.sl_avail + shoelace_arrive.arr_quant
FROM shoelace_arrive shoelace_arrive,
     shoelace_data shoelace_data,
     shoelace_data s
WHERE s.sl_name = shoelace_arrive.sl_name
AND shoelace_data.sl_name = s.sl_name;
```

The result is that data coming from one relation inserted into another, changed into updates on a third, changed into updating a fourth plus logging that final update in a fifth gets reduced into two queries.

There is a little detail that’s a bit ugly. Looking at the two queries, it turns out that the `shoelace_data` relation appears twice in the range table where it could definitely be reduced to one. The planner does not handle it and so the execution plan for the rule systems output of the `INSERT` will be

```
Nested Loop
  -> Merge Join
     -> Seq Scan
        -> Sort
        -> Seq Scan on s
     -> Seq Scan
        -> Sort
        -> Seq Scan on shoelace_arrive
     -> Seq Scan on shoelace_data
```

while omitting the extra range table entry would result in a

```
Merge Join
  -> Seq Scan
     -> Sort
     -> Seq Scan on s
     -> Seq Scan
        -> Sort
        -> Seq Scan on shoelace_arrive
```

which produces exactly the same entries in the log table. Thus, the rule system caused one extra scan on the table `shoelace_data` that is absolutely not necessary. And the same redundant scan is done once more in the `UPDATE`. But it was a really hard job to make that all possible at all.

Now we make a final demonstration of the PostgreSQL rule system and its power. Say you add some shoelaces with extraordinary colors to your database:
We would like to make a view to check which shoelace entries do not fit any shoe in color. The view for this is:

```
CREATE VIEW shoelace_mismatch AS
    SELECT * FROM shoelace WHERE NOT EXISTS
        (SELECT shoename FROM shoe WHERE slcolor = sl_color);
```

Its output is:

```
SELECT * FROM shoelace_mismatch;
```

```
<table>
<thead>
<tr>
<th>sl_name</th>
<th>sl_avail</th>
<th>sl_color</th>
<th>sl_len</th>
<th>sl_unit</th>
<th>sl_len_cm</th>
</tr>
</thead>
<tbody>
<tr>
<td>sl9</td>
<td>0</td>
<td>pink</td>
<td>35</td>
<td>inch</td>
<td>88.9</td>
</tr>
<tr>
<td>sl10</td>
<td>1000</td>
<td>magenta</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
</tbody>
</table>
```

Now we want to set it up so that mismatching shoelaces that are not in stock are deleted from the database. To make it a little harder for PostgreSQL, we don’t delete it directly. Instead we create one more view:

```
CREATE VIEW shoelace_can_delete AS
    SELECT * FROM shoelace_mismatch WHERE sl_avail = 0;
```

and do it this way:

```
DELETE FROM shoelace WHERE EXISTS
    (SELECT * FROM shoelace_can_delete
        WHERE sl_name = shoelace.sl_name);
```

Voilà:

```
SELECT * FROM shoelace;
```

```
<table>
<thead>
<tr>
<th>sl_name</th>
<th>sl_avail</th>
<th>sl_color</th>
<th>sl_len</th>
<th>sl_unit</th>
<th>sl_len_cm</th>
</tr>
</thead>
<tbody>
<tr>
<td>sl1</td>
<td>5</td>
<td>black</td>
<td>80</td>
<td>cm</td>
<td>80</td>
</tr>
<tr>
<td>sl2</td>
<td>6</td>
<td>black</td>
<td>100</td>
<td>cm</td>
<td>100</td>
</tr>
<tr>
<td>sl7</td>
<td>6</td>
<td>brown</td>
<td>60</td>
<td>cm</td>
<td>60</td>
</tr>
<tr>
<td>sl4</td>
<td>8</td>
<td>black</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl3</td>
<td>10</td>
<td>black</td>
<td>35</td>
<td>inch</td>
<td>88.9</td>
</tr>
<tr>
<td>sl8</td>
<td>21</td>
<td>brown</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl10</td>
<td>1000</td>
<td>magenta</td>
<td>40</td>
<td>inch</td>
<td>101.6</td>
</tr>
<tr>
<td>sl5</td>
<td>4</td>
<td>brown</td>
<td>1</td>
<td>m</td>
<td>100</td>
</tr>
<tr>
<td>sl6</td>
<td>20</td>
<td>brown</td>
<td>0.9</td>
<td>m</td>
<td>90</td>
</tr>
</tbody>
</table>
```

A DELETE on a view, with a subquery qualification that in total uses 4 nesting/joined views, where one of them itself has a subquery qualification containing a view and where calculated view columns are used, gets rewritten into one single query tree that deletes the requested data from a real table.

There are probably only a few situations out in the real world where such a construct is necessary. But it makes you feel comfortable that it works.
Chapter 36. The Rule System

36.4. Rules and Privileges

Due to rewriting of queries by the PostgreSQL rule system, other tables/views than those used in the original query get accessed. When update rules are used, this can include write access to tables.

Rewrite rules don’t have a separate owner. The owner of a relation (table or view) is automatically the owner of the rewrite rules that are defined for it. The PostgreSQL rule system changes the behavior of the default access control system. Relations that are used due to rules get checked against the privileges of the rule owner, not the user invoking the rule. This means that a user only needs the required privileges for the tables/views that he names explicitly in his queries.

For example: A user has a list of phone numbers where some of them are private, the others are of interest for the secretary of the office. He can construct the following:

```
CREATE TABLE phone_data (person text, phone text, private boolean);
CREATE VIEW phone_number AS
    SELECT person, CASE WHEN NOT private THEN phone END AS phone
    FROM phone_data;
GRANT SELECT ON phone_number TO secretary;
```

Nobody except him (and the database superusers) can access the `phone_data` table. But because of the `GRANT`, the secretary can run a `SELECT` on the `phone_number` view. The rule system will rewrite the `SELECT` from `phone_number` into a `SELECT` from `phone_data`. Since the user is the owner of `phone_number` and therefore the owner of the rule, the read access to `phone_data` is now checked against his privileges and the query is permitted. The check for accessing `phone_number` is also performed, but this is done against the invoking user, so nobody but the user and the secretary can use it.

The privileges are checked rule by rule. So the secretary is for now the only one who can see the public phone numbers. But the secretary can setup another view and grant access to that to the public. Then, anyone can see the `phone_number` data through the secretary’s view. What the secretary cannot do is to create a view that directly accesses `phone_data`. (Actually he can, but it will not work since every access will be denied during the permission checks.) And as soon as the user will notice, that the secretary opened his `phone_number` view, he can revoke his access. Immediately, any access to the secretary’s view would fail.

One might think that this rule-by-rule checking is a security hole, but in fact it isn’t. But if it did not work this way, the secretary could set up a table with the same columns as `phone_number` and copy the data to there once per day. Then it’s his own data and he can grant access to everyone he wants. A `GRANT` command means, “I trust you”. If someone you trust does the thing above, it’s time to think it over and then use `REVOKE`.

Note that while views can be used to hide the contents of certain columns using the technique shown above, they cannot be used to reliably conceal the data in unseen rows. For example, the following view is insecure:

```
CREATE VIEW phone_number AS
    SELECT person, phone FROM phone_data WHERE phone NOT LIKE '412%';
```

This view might seem secure, since the rule system will rewrite any `SELECT` from `phone_number` into a `SELECT` from `phone_data` and add the qualification that only entries where `phone` does not begin with 412 are wanted. But if the user can create his or her own functions, it is not difficult to convince the planner to execute the user-defined function prior to the `NOT LIKE` expression.

```
CREATE FUNCTION tricky(text, text) RETURNS bool AS $$
BEGIN
    RAISE NOTICE '% => %', $1, $2;
$$;
```

Note that while views can be used to hide the contents of certain columns using the technique shown above, they cannot be used to reliably conceal the data in unseen rows. For example, the following view is insecure:

```
CREATE VIEW phone_number AS
    SELECT person, phone FROM phone_data WHERE phone NOT LIKE '412%';
```

This view might seem secure, since the rule system will rewrite any `SELECT` from `phone_number` into a `SELECT` from `phone_data` and add the qualification that only entries where `phone` does not begin with 412 are wanted. But if the user can create his or her own functions, it is not difficult to convince the planner to execute the user-defined function prior to the `NOT LIKE` expression.

```
CREATE FUNCTION tricky(text, text) RETURNS bool AS $$
BEGIN
    RAISE NOTICE '% => %', $1, $2;
$$
```
Chapter 36. The Rule System

```sql
RETURN true;
END
$$ LANGUAGE plpgsql COST 0.0000000000000000000001;
SELECT * FROM phone_number WHERE tricky(person, phone);
```

Every person and phone number in the `phone_data` table will be printed as a NOTICE, because the planner will choose to execute the inexpensive `tricky` function before the more expensive NOT LIKE. Even if the user is prevented from defining new functions, built-in functions can be used in similar attacks. (For example, casting functions include their inputs in the error messages they produce.)

Similar considerations apply to update rules. In the examples of the previous section, the owner of the tables in the example database could grant the privileges SELECT, INSERT, UPDATE, and DELETE on the `shoelace` view to someone else, but only SELECT on `shoelace_log`. The rule action to write log entries will still be executed successfully, and that other user could see the log entries. But he cannot create fake entries, nor could he manipulate or remove existing ones. In this case, there is no possibility of subverting the rules by convincing the planner to alter the order of operations, because the only rule which references `shoelace_log` is an unqualified INSERT. This might not be true in more complex scenarios.

36.5. Rules and Command Status

The PostgreSQL server returns a command status string, such as `INSERT 149592 1`, for each command it receives. This is simple enough when there are no rules involved, but what happens when the query is rewritten by rules?

Rules affect the command status as follows:

- If there is no unconditional INSTEAD rule for the query, then the originally given query will be executed, and its command status will be returned as usual. (But note that if there were any conditional INSTEAD rules, the negation of their qualifications will have been added to the original query. This might reduce the number of rows it processes, and if so the reported status will be affected.)
- If there is any unconditional INSTEAD rule for the query, then the original query will not be executed at all. In this case, the server will return the command status for the last query that was inserted by an INSTEAD rule (conditional or unconditional) and is of the same command type (INSERT, UPDATE, or DELETE) as the original query. If no query meeting those requirements is added by any rule, then the returned command status shows the original query type and zeroes for the row-count and OID fields.

(This system was established in PostgreSQL 7.3. In versions before that, the command status might show different results when rules exist.)

The programmer can ensure that any desired INSTEAD rule is the one that sets the command status in the second case, by giving it the alphabetically last rule name among the active rules, so that it gets applied last.

36.6. Rules versus Triggers

Many things that can be done using triggers can also be implemented using the PostgreSQL rule system. One of the things that cannot be implemented by rules are some kinds of constraints, especially foreign keys. It is possible to place a qualified rule that rewrites a command to NOTHING if the value
Chapter 36. The Rule System

of a column does not appear in another table. But then the data is silently thrown away and that’s not a good idea. If checks for valid values are required, and in the case of an invalid value an error message should be generated, it must be done by a trigger.

On the other hand, a trigger that is fired on INSERT on a view can do the same as a rule: put the data somewhere else and suppress the insert in the view. But it cannot do the same thing on UPDATE or DELETE, because there is no real data in the view relation that could be scanned, and thus the trigger would never get called. Only a rule will help.

For the things that can be implemented by both, which is best depends on the usage of the database. A trigger is fired for any affected row once. A rule manipulates the query or generates an additional query. So if many rows are affected in one statement, a rule issuing one extra command is likely to be faster than a trigger that is called for every single row and must execute its operations many times. However, the trigger approach is conceptually far simpler than the rule approach, and is easier for novices to get right.

Here we show an example of how the choice of rules versus triggers plays out in one situation. There are two tables:

```sql
CREATE TABLE computer {
    hostname text, -- indexed
    manufacturer text -- indexed
};

CREATE TABLE software {
    software text, -- indexed
    hostname text -- indexed
};
```

Both tables have many thousands of rows and the indexes on `hostname` are unique. The rule or trigger should implement a constraint that deletes rows from `software` that reference a deleted computer. The trigger would use this command:

```sql
DELETE FROM software WHERE hostname = $1;
```

Since the trigger is called for each individual row deleted from `computer`, it can prepare and save the plan for this command and pass the `hostname` value in the parameter. The rule would be written as:

```sql
CREATE RULE computer_del AS ON DELETE TO computer
    DO DELETE FROM software WHERE hostname = OLD.hostname;
```

Now we look at different types of deletes. In the case of a:

```sql
DELETE FROM computer WHERE hostname = 'mypc.local.net';
```

the table `computer` is scanned by index (fast), and the command issued by the trigger would also use an index scan (also fast). The extra command from the rule would be:

```sql
DELETE FROM software WHERE computer.hostname = 'mypc.local.net'
    AND software.hostname = computer.hostname;
```

Since there are appropriate indexes setup, the planner will create a plan of

```
Nestloop
  -> Index Scan using comp_hostidx on computer
  -> Index Scan using soft_hostidx on software
```
So there would be not that much difference in speed between the trigger and the rule implementation.

With the next delete we want to get rid of all the 2000 computers where the hostname starts with old. There are two possible commands to do that. One is:

```sql
DELETE FROM computer WHERE hostname >= 'old'
    AND hostname < 'ole'
```

The command added by the rule will be:

```sql
DELETE FROM software WHERE computer.hostname >= 'old' AND computer.hostname < 'ole'
    AND software.hostname = computer.hostname;
```

with the plan

```
Hash Join
  -> Seq Scan on software
  -> Hash
    -> Index Scan using comp_hostidx on computer
```

The other possible command is:

```sql
DELETE FROM computer WHERE hostname ~ '^old';
```

which results in the following executing plan for the command added by the rule:

```
Nestloop
  -> Index Scan using comp_hostidx on computer
  -> Index Scan using soft_hostidx on software
```

This shows, that the planner does not realize that the qualification for hostname in computer could also be used for an index scan on software when there are multiple qualification expressions combined with AND, which is what it does in the regular-expression version of the command. The trigger will get invoked once for each of the 2000 old computers that have to be deleted, and that will result in one index scan over computer and 2000 index scans over software. The rule implementation will do it with two commands that use indexes. And it depends on the overall size of the table software whether the rule will still be faster in the sequential scan situation. 2000 command executions from the trigger over the SPI manager take some time, even if all the index blocks will soon be in the cache.

The last command we look at is:

```sql
DELETE FROM computer WHERE manufacturer = 'bim';
```

Again this could result in many rows to be deleted from computer. So the trigger will again run many commands through the executor. The command generated by the rule will be:

```sql
DELETE FROM software WHERE computer.manufacturer = 'bim'
    AND software.hostname = computer.hostname;
```

The plan for that command will again be the nested loop over two index scans, only using a different index on computer:

```
Nestloop
  -> Index Scan using comp_manufidx on computer
  -> Index Scan using soft_hostidx on software
```

In any of these cases, the extra commands from the rule system will be more or less independent from the number of affected rows in a command.
The summary is, rules will only be significantly slower than triggers if their actions result in large and badly qualified joins, a situation where the planner fails.
Chapter 37. Procedural Languages

PostgreSQL allows user-defined functions to be written in other languages besides SQL and C. These other languages are generically called procedural languages (PLs). For a function written in a procedural language, the database server has no built-in knowledge about how to interpret the function’s source text. Instead, the task is passed to a special handler that knows the details of the language. The handler could either do all the work of parsing, syntax analysis, execution, etc. itself, or it could serve as “glue” between PostgreSQL and an existing implementation of a programming language. The handler itself is a C language function compiled into a shared object and loaded on demand, just like any other C function.

There are currently four procedural languages available in the standard PostgreSQL distribution: PL/pgSQL (Chapter 38), PL/Tcl (Chapter 39), PL/Perl (Chapter 40), and PL/Python (Chapter 41). There are additional procedural languages available that are not included in the core distribution. Appendix G has information about finding them. In addition other languages can be defined by users; the basics of developing a new procedural language are covered in Chapter 48.

37.1. Installing Procedural Languages

A procedural language must be “installed” into each database where it is to be used. But procedural languages installed in the database template1 are automatically available in all subsequently created databases, since their entries in template1 will be copied by CREATE DATABASE. So the database administrator can decide which languages are available in which databases and can make some languages available by default if he chooses.

For the languages supplied with the standard distribution, it is only necessary to execute CREATE LANGUAGE language_name to install the language into the current database. Alternatively, the program createlang can be used to do this from the shell command line. For example, to install the language PL/pgSQL into the database template1, use:

```sql
createlang plpgsql template1
```

The manual procedure described below is only recommended for installing custom languages that CREATE LANGUAGE does not know about.

Manual Procedural Language Installation

A procedural language is installed in a database in four steps, which must be carried out by a database superuser. (For languages known to CREATE LANGUAGE, the second and third steps can be omitted, because they will be carried out automatically if needed.)

1. The shared object for the language handler must be compiled and installed into an appropriate library directory. This works in the same way as building and installing modules with regular user-defined C functions does; see Section 34.9.6. Often, the language handler will depend on an external library that provides the actual programming language engine; if so, that must be installed as well.

2. The handler must be declared with the command

```sql
CREATE FUNCTION handler_function_name() RETURNS language_handler AS 'path-to-shared-object'
LANGUAGE C;
```
Chapter 37. Procedural Languages

The special return type of `language_handler` tells the database system that this function does not return one of the defined SQL data types and is not directly usable in SQL statements.

3. Optionally, the language handler can provide a “validator” function that checks a function definition for correctness without actually executing it. The validator function is called by `CREATE FUNCTION` if it exists. If a validator function is provided by the handler, declare it with a command like

   ```sql
   CREATE FUNCTION validator_function_name(oid)
   RETURNS void
   AS 'path-to-shared-object'
   LANGUAGE C;
   ```

4. The PL must be declared with the command

   ```sql
   CREATE [TRUSTED] [PROCEDURAL] LANGUAGE language-name
   HANDLER handler_function_name
   [VALIDATOR validator_function_name] ;
   ```

   The optional key word `TRUSTED` specifies that ordinary database users that have no superuser privileges should be allowed to use this language to create functions and trigger procedures. Since PL functions are executed inside the database server, the `TRUSTED` flag should only be given for languages that do not allow access to database server internals or the file system. The languages PL/pgSQL, PL/Tcl, and PL/Perl are considered trusted; the languages PL/TclU, PL/PerlU, and PL/PythonU are designed to provide unlimited functionality and should not be marked trusted.

Example 37-1 shows how the manual installation procedure would work with the language PL/pgSQL.

**Example 37-1. Manual Installation of PL/pgSQL**

The following command tells the database server where to find the shared object for the PL/pgSQL language’s call handler function.

   ```sql
   CREATE FUNCTION plpgsql_call_handler() RETURNS language_handler AS
   '$libdir/plpgsql' LANGUAGE C;
   ```

   PL/pgSQL has a validator function, so we declare that too:

   ```sql
   CREATE FUNCTION plpgsql_validator(oid) RETURNS void AS
   '$libdir/plpgsql' LANGUAGE C;
   ```

   The command:

   ```sql
   CREATE TRUSTED PROCEDURAL LANGUAGE plpgsql
   HANDLER plpgsql_call_handler
   VALIDATOR plpgsql_validator;
   ```

   then defines that the previously declared functions should be invoked for functions and trigger procedures where the language attribute is `plpgsql`.

In a default PostgreSQL installation, the handler for the PL/pgSQL language is built and installed into the “library” directory. If Tcl support is configured in, the handlers for PL/Tcl and PL/TclU are also built and installed in the same location. Likewise, the PL/Perl and PL/PerlU handlers are built and installed if Perl support is configured, and the PL/PythonU handler is installed if Python support is configured.
Chapter 38. PL/pgSQL - SQL Procedural Language

38.1. Overview

PL/pgSQL is a loadable procedural language for the PostgreSQL database system. The design goals of PL/pgSQL were to create a loadable procedural language that

- can be used to create functions and trigger procedures,
- adds control structures to the SQL language,
- can perform complex computations,
- inherits all user-defined types, functions, and operators,
- can be defined to be trusted by the server,
- is easy to use.

Functions created with PL/pgSQL can be used anywhere that built-in functions could be used. For example, it is possible to create complex conditional computation functions and later use them to define operators or use them in index expressions.

38.1.1. Advantages of Using PL/pgSQL

SQL is the language PostgreSQL and most other relational databases use as query language. It’s portable and easy to learn. But every SQL statement must be executed individually by the database server.

That means that your client application must send each query to the database server, wait for it to be processed, receive and process the results, do some computation, then send further queries to the server. All this incurs interprocess communication and will also incur network overhead if your client is on a different machine than the database server.

With PL/pgSQL you can group a block of computation and a series of queries inside the database server, thus having the power of a procedural language and the ease of use of SQL, but with considerable savings of client/server communication overhead.

- Extra round trips between client and server are eliminated
- Intermediate results that the client does not need do not have to be marshaled or transferred between server and client
- Multiple rounds of query parsing can be avoided

This can result in a considerable performance increase as compared to an application that does not use stored functions.

Also, with PL/pgSQL you can use all the data types, operators and functions of SQL.
38.1.2. Supported Argument and Result Data Types

Functions written in PL/pgSQL can accept as arguments any scalar or array data type supported by the server, and they can return a result of any of these types. They can also accept or return any composite type (row type) specified by name. It is also possible to declare a PL/pgSQL function as returning record, which means that the result is a row type whose columns are determined by specification in the calling query, as discussed in Section 7.2.1.4.

PL/pgSQL functions can also be declared to accept and return the polymorphic types arelement, anyarray, anynonarray, and anyenum. The actual data types handled by a polymorphic function can vary from call to call, as discussed in Section 34.2.5. An example is shown in Section 38.3.1.

PL/pgSQL functions can also be declared to return a “set” (or table) of any data type that can be returned as a single instance. Such a function generates its output by executing RETURN NEXT for each desired element of the result set, or by using RETURN QUERY to output the result of evaluating a query.

Finally, a PL/pgSQL function can be declared to return void if it has no useful return value.

PL/pgSQL functions can also be declared with output parameters in place of an explicit specification of the return type. This does not add any fundamental capability to the language, but it is often convenient, especially for returning multiple values.

Specific examples appear in Section 38.3.1 and Section 38.6.1.

38.2. Structure of PL/pgSQL

PL/pgSQL is a block-structured language. The complete text of a function definition must be a block. A block is defined as:

```
[ [<<label>>] ]
[ DECLARE declarations ]
BEGIN
 statements
END [ [ label ] ];
```

Each declaration and each statement within a block is terminated by a semicolon. A block that appears within another block must have a semicolon after END, as shown above; however the final END that concludes a function body does not require a semicolon.

**Tip:** A common mistake is to write a semicolon immediately after BEGIN. This is incorrect and will result in a syntax error.

A *label* is only needed if you want to identify the block for use in an EXIT statement, or to qualify the names of the variables declared in the block. If a label is given after END, it must match the label at the block’s beginning.

All key words are case-insensitive. Identifiers are implicitly converted to lowercase unless double-quoted, just as they are in ordinary SQL commands.

There are two types of comments in PL/pgSQL. A double dash (--) starts a comment that extends to the end of the line. A /* starts a block comment that extends to the next occurrence of */. Block
comments cannot be nested, but double dash comments can be enclosed into a block comment and a
double dash can hide the block comment delimiters /* and */.

Any statement in the statement section of a block can be a subblock. Subblocks can be used for logical
grouping or to localize variables to a small group of statements. Variables declared in a subblock mask
any similarly-named variables of outer blocks for the duration of the subblock; but you can access the
outer variables anyway if you qualify their names with their block’s label. For example:

```plpgsql
CREATE FUNCTION somefunc() RETURNS integer AS $$
<< outerblock >>
DECLARE
  quantity integer := 30;
BEGIN
  RAISE NOTICE 'Quantity here is %', quantity; -- Prints 30
  quantity := 50;
  --
  -- Create a subblock
  --
  DECLARE
    quantity integer := 80;
  BEGIN
    RAISE NOTICE 'Quantity here is %', quantity; -- Prints 80
    RAISE NOTICE 'Outer quantity here is %', outerblock.quantity; -- Prints 50
  END;
  RAISE NOTICE 'Quantity here is %', quantity; -- Prints 50

RETURN quantity;
END;
$$ LANGUAGE plpgsql;
```

**Note:** There is actually a hidden “outer block” surrounding the body of any PL/pgSQL function.
This block provides the declarations of the function’s parameters (if any), as well as some special
variables such as `FOUND` (see Section 38.5.5). The outer block is labeled with the function’s name,
meaning that parameters and special variables can be qualified with the function’s name.

It is important not to confuse the use of `BEGIN/END` for grouping statements in PL/pgSQL with the
similarly-named SQL commands for transaction control. PL/pgSQL’s `BEGIN/END` are only for group-
ing; they do not start or end a transaction. Functions and trigger procedures are always executed within
a transaction established by an outer query — they cannot start or commit that transaction, since there
would be no context for them to execute in. However, a block containing an `EXCEPTION` clause effec-
tively forms a subtransaction that can be rolled back without affecting the outer transaction. For more
about that see Section 38.6.5.

### 38.3. Declarations

All variables used in a block must be declared in the declarations section of the block. (The only
exception is that the loop variable of a `FOR` loop iterating over a range of integer values is automatically
declared as an integer variable.)

PL/pgSQL variables can have any SQL data type, such as `integer`, `varchar`, and `char`. 
Chapter 38. PL/pgSQL - SQL Procedural Language

Here are some examples of variable declarations:

user_id integer;
quantity numeric(5);
url varchar;
myrow tablename%ROWTYPE;
myfield tablename.columnname%TYPE;
aro RECORD;

The general syntax of a variable declaration is:

The DEFAULT clause, if given, specifies the initial value assigned to the variable when the block is entered. If the DEFAULT clause is not given then the variable is initialized to the SQL null value. The CONSTANT option prevents the variable from being assigned to, so that its value remains constant for the duration of the block. If NOT NULL is specified, an assignment of a null value results in a run-time error. All variables declared as NOT NULL must have a nonnull default value specified.

A variable’s default value is evaluated and assigned to the variable each time the block is entered (not just once per function call). So, for example, assigning now() to a variable of type timestamp causes the variable to have the time of the current function call, not the time when the function was precompiled.

Examples:

quantity integer DEFAULT 32;
url varchar := 'http://mysite.com';
user_id CONSTANT integer := 10;

38.3.1. Aliases for Function Parameters

Parameters passed to functions are named with the identifiers $1, $2, etc. Optionally, aliases can be declared for $n parameter names for increased readability. Either the alias or the numeric identifier can then be used to refer to the parameter value.

There are two ways to create an alias. The preferred way is to give a name to the parameter in the CREATE FUNCTION command, for example:

CREATE FUNCTION sales_tax(subtotal real) RETURNS real AS $$
BEGIN
    RETURN subtotal * 0.06;
END;
$$ LANGUAGE plpgsql;

The other way, which was the only way available before PostgreSQL 8.0, is to explicitly declare an alias, using the declaration syntax

name ALIAS FOR $n;

The same example in this style looks like:

CREATE FUNCTION sales_tax(real) RETURNS real AS $$
DECLARE
Chapter 38. PL/pgSQL - SQL Procedural Language

subtotal ALIAS FOR $1;
BEGIN
RETURN subtotal * 0.06;
END;
$$ LANGUAGE plpgsql;

Note: These two examples are not perfectly equivalent. In the first case, subtotal could be referenced as sales_tax.subtotal, but in the second case it could not. (Had we attached a label to the block, subtotal could be qualified with that label, instead.)

Some more examples:

CREATE FUNCTION instr(varchar, integer) RETURNS integer AS $$
DECLARE
  v_string ALIAS FOR $1;
  index ALIAS FOR $2;
BEGIN
  -- some computations using v_string and index here
END;
$$ LANGUAGE plpgsql;

CREATE FUNCTION concat_selected_fields(in_t sometablename) RETURNS text AS $$
BEGIN
RETURN in_t.f1 || in_t.f3 || in_t.f5 || in_t.f7;
END;
$$ LANGUAGE plpgsql;

When a PL/pgSQL function is declared with output parameters, the output parameters are given names and optional aliases in just the same way as the normal input parameters. An output parameter is effectively a variable that starts out NULL; it should be assigned to during the execution of the function. The final value of the parameter is what is returned. For instance, the sales-tax example could also be done this way:

CREATE FUNCTION sales_tax(subtotal real, OUT tax real) AS $$
BEGIN
  tax := subtotal * 0.06;
END;
$$ LANGUAGE plpgsql;

Notice that we omitted RETURNS real — we could have included it, but it would be redundant.

Output parameters are most useful when returning multiple values. A trivial example is:

CREATE FUNCTION sum_n_product(x int, y int, OUT sum int, OUT prod int) AS $$
BEGIN
  sum := x + y;
  prod := x * y;
END;
$$ LANGUAGE plpgsql;

As discussed in Section 34.4.3, this effectively creates an anonymous record type for the function’s results. If a RETURNS clause is given, it must say RETURNS record.
When the return type of a PL/pgSQL function is declared as a polymorphic type (anycolumn, anyarray, anynonarray, or anyenum), a special parameter $0$ is created. Its data type is the actual return type of the function, as deduced from the actual input types (see Section 34.2.5). This allows the function to access its actual return type as shown in Section 38.3.2. $0$ is initialized to null and can be modified by the function, so it can be used to hold the return value if desired, though that is not required. $0$ can also be given an alias. For example, this function works on any data type that has a + operator:

```sql
CREATE FUNCTION add_three_values(v1 anyelement, v2 anyelement, v3 anyelement)
RETURNS anyelement AS $$
DECLARE
    result ALIAS FOR $0;
BEGIN
    result := v1 + v2 + v3;
    RETURN result;
END;
$$ LANGUAGE plpgsql;
```

The same effect can be had by declaring one or more output parameters as polymorphic types. In this case the special $0$ parameter is not used; the output parameters themselves serve the same purpose. For example:

```sql
CREATE FUNCTION add_three_values(v1 anyelement, v2 anyelement, v3 anyelement,
    OUT sum anyelement)
AS $$
BEGIN
    sum := v1 + v2 + v3;
END;
$$ LANGUAGE plpgsql;
```

### 38.3.2. Copying Types

**variable%TYPE**

%TYPE provides the data type of a variable or table column. You can use this to declare variables that will hold database values. For example, let’s say you have a column named `user_id` in your `users` table. To declare a variable with the same data type as `users.user_id` you write:

```sql
user_id users.user_id%TYPE;
```

By using %TYPE you don’t need to know the data type of the structure you are referencing, and most importantly, if the data type of the referenced item changes in the future (for instance: you change the type of `user_id` from `integer` to `real`), you might not need to change your function definition.

%TYPE is particularly valuable in polymorphic functions, since the data types needed for internal variables can change from one call to the next. Appropriate variables can be created by applying %TYPE to the function’s arguments or result placeholders.
38.3.3. Row Types

A variable of a composite type is called a row variable (or row-type variable). Such a variable can hold a whole row of a SELECT or FOR query result, so long as that query’s column set matches the declared type of the variable. The individual fields of the row value are accessed using the usual dot notation, for example rowvar.field.

A row variable can be declared to have the same type as the rows of an existing table or view, by using the table_name%ROWTYPE notation; or it can be declared by giving a composite type’s name. (Since every table has an associated composite type of the same name, it actually does not matter in PostgreSQL whether you write %ROWTYPE or not. But the form with %ROWTYPE is more portable.)

Parameters to a function can be composite types (complete table rows). In that case, the corresponding identifier $n will be a row variable, and fields can be selected from it, for example $1.user_id.

Parameters to a function can be composite types (complete table rows). In that case, the corresponding identifier $n will be a row variable, and fields can be selected from it, for example $1.user_id.

Parameters to a function can be composite types (complete table rows). In that case, the corresponding identifier $n will be a row variable, and fields can be selected from it, for example $1.user_id.

Parameters to a function can be composite types (complete table rows). In that case, the corresponding identifier $n will be a row variable, and fields can be selected from it, for example $1.user_id.

Here is an example of using composite types. table1 and table2 are existing tables having at least the mentioned fields:

```
CREATE FUNCTION merge_fields(t_row table1) RETURNS text AS $$
DECLARE
    t2_row table2%ROWTYPE;
BEGIN
    SELECT * INTO t2_row FROM table2 WHERE ... ;
    RETURN t_row.f1 || t2_row.f3 || t_row.f5 || t2_row.f7;
END;
$$ LANGUAGE plpgsql;

SELECT merge_fields(t.*) FROM table1 t WHERE ... ;
```

38.3.4. Record Types

Record variables are similar to row-type variables, but they have no predefined structure. They take on the actual row structure of the row they are assigned during a SELECT or FOR command. The substructure of a record variable can change each time it is assigned to. A consequence of this is that until a record variable is first assigned to, it has no substructure, and any attempt to access a field in it will draw a run-time error.

Note that RECORD is not a true data type, only a placeholder. One should also realize that when a PL/pgSQL function is declared to return type record, this is not quite the same concept as a record variable, even though such a function might use a record variable to hold its result. In both cases the actual row structure is unknown when the function is written, but for a function returning record the actual structure is determined when the calling query is parsed, whereas a record variable can change its row structure on-the-fly.
38.3.5. RENAME

RENAME oldname TO newname;

Using the RENAME declaration you can change the name of a variable, record or row. This is primarily useful if NEW or OLD should be referenced by another name inside a trigger procedure. See also ALIAS.

Examples:

RENAME id TO user_id;
RENAME this_var TO that_var;

Note: RENAME appears to be broken as of PostgreSQL 7.3. Fixing this is of low priority, since ALIAS covers most of the practical uses of RENAME.

38.4. Expressions

All expressions used in PL/pgSQL statements are processed using the server’s main SQL executor. For example, when you write a PL/pgSQL statement like

IF expression THEN ...

PL/pgSQL will evaluate the expression by feeding a query like

SELECT expression

to the main SQL engine. While forming the SELECT command, any occurrences of PL/pgSQL variable names are replaced by parameters, as discussed in detail in Section 38.10.1. This allows the query plan for the SELECT to be prepared just once and then reused for subsequent evaluations with different values of the variables. Thus, what really happens on first use of an expression is essentially a PREPARE command. For example, if we have declared two integer variables \( x \) and \( y \), and we write

IF \( x < y \) THEN ...

what happens behind the scenes is

PREPARE statement_name(integer, integer) AS SELECT $1 < $2;

and then this prepared statement is EXECUTED for each execution of the IF statement, with the current values of the PL/pgSQL variables supplied as parameter values. The query plan prepared in this way is saved for the life of the database connection, as described in Section 38.10.2. Normally these details are not important to a PL/pgSQL user, but they are useful to know when trying to diagnose a problem.

38.5. Basic Statements

In this section and the following ones, we describe all the statement types that are explicitly understood by PL/pgSQL. Anything not recognized as one of these statement types is presumed to be an
SQL command and is sent to the main database engine to execute, as described in Section 38.5.2 and Section 38.5.3.

### 38.5.1. Assignment

An assignment of a value to a PL/pgSQL variable or row/record field is written as:

```sql
variable := expression;
```

As explained above, the expression in such a statement is evaluated by means of an SQL `SELECT` command sent to the main database engine. The expression must yield a single value.

If the expression’s result data type doesn’t match the variable’s data type, or the variable has a specific size/precision (like `char(20)`), the result value will be implicitly converted by the PL/pgSQL interpreter using the result type’s output-function and the variable type’s input-function. Note that this could potentially result in run-time errors generated by the input function, if the string form of the result value is not acceptable to the input function.

Examples:

```sql
tax := subtotal * 0.06;
my_record.user_id := 20;
```

### 38.5.2. Executing a Command With No Result

For any SQL command that does not return rows, for example `INSERT` without a `RETURNING` clause, you can execute the command within a PL/pgSQL function just by writing the command.

Any PL/pgSQL variable name appearing in the command text is replaced by a parameter symbol, and then the current value of the variable is provided as the parameter value at run time. This is exactly like the processing described earlier for expressions; for details see Section 38.10.1. As an example, if you write:

```sql
DECLARE
  key TEXT;
  delta INTEGER;
BEGIN
  ...
  UPDATE mytab SET val = val + delta WHERE id = key;
```

the command text seen by the main SQL engine will look like:

```sql
UPDATE mytab SET val = val + $1 WHERE id = $2;
```

Although you don’t normally have to think about this, it’s helpful to know it when you need to make sense of syntax-error messages.
Caution

PL/pgSQL will substitute for any identifier matching one of the function’s declared variables; it is not bright enough to know whether that’s what you meant! Thus, it is a bad idea to use a variable name that is the same as any table, column, or function name that you need to reference in commands within the function. For more discussion see Section 38.10.1.

When executing a SQL command in this way, PL/pgSQL plans the command just once and re-uses the plan on subsequent executions, for the life of the database connection. The implications of this are discussed in detail in Section 38.10.2.

Sometimes it is useful to evaluate an expression or SELECT query but discard the result, for example when calling a function that has side-effects but no useful result value. To do this in PL/pgSQL, use the PERFORM statement:

```
PERFORM query;
```

This executes `query` and discards the result. Write the `query` the same way you would write an SQL SELECT command, but replace the initial keyword SELECT with PERFORM. PL/pgSQL variables will be substituted into the query just as for commands that return no result, and the plan is cached in the same way. Also, the special variable FOUND is set to true if the query produced at least one row, or false if it produced no rows (see Section 38.5.5).

**Note:** One might expect that writing SELECT directly would accomplish this result, but at present the only accepted way to do it is PERFORM. A SQL command that can return rows, such as SELECT, will be rejected as an error unless it has an INTO clause as discussed in the next section.

An example:

```
PERFORM create_mv('cs_session_page_requests_mv', my_query);
```

### 38.5.3. Executing a Query with a Single-Row Result

The result of a SQL command yielding a single row (possibly of multiple columns) can be assigned to a record variable, row-type variable, or list of scalar variables. This is done by writing the base SQL command and adding an INTO clause. For example,

```
SELECT select_expressions INTO [STRICT] target FROM ...;
INSERT ... RETURNING expressions INTO [STRICT] target;
UPDATE ... RETURNING expressions INTO [STRICT] target;
DELETE ... RETURNING expressions INTO [STRICT] target;
```

where `target` can be a record variable, a row variable, or a comma-separated list of simple variables and record/row fields. PL/pgSQL variables will be substituted into the rest of the query, and the plan is cached, just as described above for commands that do not return rows. This works for SELECT, INSERT/UPDATE/DELETE with RETURNING, and utility commands that return row-set results (such as EXPLAIN). Except for the INTO clause, the SQL command is the same as it would be written outside PL/pgSQL.
Tip: Note that this interpretation of `SELECT with INTO` is quite different from PostgreSQL's regular `SELECT INTO` command, wherein the INTO target is a newly created table. If you want to create a table from a SELECT result inside a PL/pgSQL function, use the syntax `CREATE TABLE ... AS SELECT`.

If a row or a variable list is used as target, the query’s result columns must exactly match the structure of the target as to number and data types, or a run-time error occurs. When a record variable is the target, it automatically configures itself to the row type of the query result columns.

The INTO clause can appear almost anywhere in the SQL command. Customarily it is written either just before or just after the list of `select_expressions` in a `SELECT` command, or at the end of the command for other command types. It is recommended that you follow this convention in case the PL/pgSQL parser becomes stricter in future versions.

If `STRICT` is not specified in the INTO clause, then `target` will be set to the first row returned by the query, or to nulls if the query returned no rows. (Note that “the first row” is not well-defined unless you’ve used `ORDER BY`.) Any result rows after the first row are discarded. You can check the special `FOUND` variable (see Section 38.5.5) to determine whether a row was returned:

```
SELECT * INTO myrec FROM emp WHERE empname = myname;
IF NOT FOUND THEN
    RAISE EXCEPTION 'employee % not found', myname;
END IF;
```

If the `STRICT` option is specified, the query must return exactly one row or a run-time error will be reported, either `NO_DATA_FOUND` (no rows) or `TOO_MANY_ROWS` (more than one row). You can use an exception block if you wish to catch the error, for example:

```
BEGIN
    SELECT * INTO STRICT myrec FROM emp WHERE empname = myname;
EXCEPTION
    WHEN NO_DATA_FOUND THEN
        RAISE EXCEPTION 'employee % not found', myname;
    WHEN TOO_MANY_ROWS THEN
        RAISE EXCEPTION 'employee % not unique', myname;
END;
```

Successful execution of a command with `STRICT` always sets `FOUND` to true.

For `INSERT/UPDATE/DELETE` with `RETURNING`, PL/pgSQL reports an error for more than one returned row, even when `STRICT` is not specified. This is because there is no option such as `ORDER BY` with which to determine which affected row should be returned.

Note: The `STRICT` option matches the behavior of Oracle PL/SQL's `SELECT INTO` and related statements.

To handle cases where you need to process multiple result rows from a SQL query, see Section 38.6.4.

### 38.5.4. Executing Dynamic Commands

Oftentimes you will want to generate dynamic commands inside your PL/pgSQL functions, that is, commands that will involve different tables or different data types each time they are executed.
Chapter 38. PL/pgSQL - SQL Procedural Language

PL/pgSQL’s normal attempts to cache plans for commands (as discussed in Section 38.10.2) will not work in such scenarios. To handle this sort of problem, the EXECUTE statement is provided:

```sql
EXECUTE command-string [ INTO [STRICT] target ];
```

where `command-string` is an expression yielding a string (of type `text`) containing the command to be executed and `target` is a record variable, row variable, or a comma-separated list of simple variables and record/row fields.

No substitution of PL/pgSQL variables is done on the computed command string. Any required variable values must be inserted in the command string as it is constructed.

Also, there is no plan caching for commands executed via EXECUTE. Instead, the command is prepared each time the statement is run. Thus the command string can be dynamically created within the function to perform actions on different tables and columns.

The `INTO` clause specifies where the results of a SQL command returning rows should be assigned. If a row or variable list is provided, it must exactly match the structure of the query’s results (when a record variable is used, it will configure itself to match the result structure automatically). If multiple rows are returned, only the first will be assigned to the `INTO` variable. If no rows are returned, NULL is assigned to the `INTO` variable(s). If no `INTO` clause is specified, the query results are discarded.

If the `STRICT` option is given, an error is reported unless the query produces exactly one row.

SELECT INTO is not currently supported within EXECUTE; instead, execute a plain SELECT command and specify INTO as part of the EXECUTE itself.

**Note:** The PL/pgSQL EXECUTE statement is not related to the EXECUTE SQL statement supported by the PostgreSQL server. The server’s EXECUTE statement cannot be used directly within PL/pgSQL functions (and is not needed).

When working with dynamic commands you will often have to handle escaping of single quotes. The recommended method for quoting fixed text in your function body is dollar quoting. (If you have legacy code that does not use dollar quoting, please refer to the overview in Section 38.11.1, which can save you some effort when translating said code to a more reasonable scheme.)

Dynamic values that are to be inserted into the constructed query require careful handling since they might themselves contain quote characters. An example (this assumes that you are using dollar quoting for the function as a whole, so the quote marks need not be doubled):

```sql
EXECUTE 'UPDATE tbl SET '
  || quote_ident(colname)
  || ' = ' || quote_literal(newvalue)
  || ' WHERE key = ' || quote_literal(keyvalue);
```

This example demonstrates the use of the `quote_ident` and `quote_literal` functions. For safety, expressions containing column and table identifiers should be passed to `quote_ident`. Expressions containing values that should be literal strings in the constructed command should be passed to `quote_literal`. Both take the appropriate steps to return the input text enclosed in double or single quotes respectively, with any embedded special characters properly escaped.

Note that dollar quoting is only useful for quoting fixed text. It would be a very bad idea to try to do the above example as:
EXECUTE 'UPDATE tbl SET ' || quote_ident(colname) || ' = $$' || newvalue || '$$ WHERE key = ' || quote_literal(keyvalue);  

because it would break if the contents of newvalue happened to contain $$$. The same objection would apply to any other dollar-quoting delimiter you might pick. So, to safely quote text that is not known in advance, you must use quote_literal.

A much larger example of a dynamic command and EXECUTE can be seen in Example 38-6, which builds and executes a CREATE FUNCTION command to define a new function.

### 38.5.5. Obtaining the Result Status

There are several ways to determine the effect of a command. The first method is to use the GET DIAGNOSTICS command, which has the form:

```
GET DIAGNOSTICS variable = item [ , ... ];
```

This command allows retrieval of system status indicators. Each item is a key word identifying a state value to be assigned to the specified variable (which should be of the right data type to receive it). The currently available status items are ROW_COUNT, the number of rows processed by the last SQL command sent down to the SQL engine, and RESULT_OID, the OID of the last row inserted by the most recent SQL command. Note that RESULT_OID is only useful after an INSERT command into a table containing OIDs.

An example:

```
GET DIAGNOSTICS integer_var = ROW_COUNT;
```

The second method to determine the effects of a command is to check the special variable named FOUND, which is of type boolean. FOUND starts out false within each PL/pgSQL function call. It is set by each of the following types of statements:

- A SELECT INTO statement sets FOUND true if a row is assigned, false if no row is returned.
- A PERFORM statement sets FOUND true if it produces (and discards) one or more rows, false if no row is produced.
- UPDATE, INSERT, and DELETE statements set FOUND true if at least one row is affected, false if no row is affected.
- A FETCH statement sets FOUND true if it returns a row, false if no row is returned.
- A MOVE statement sets FOUND true if it successfully repositions the cursor, false otherwise.
- A FOR statement sets FOUND true if it iterates one or more times, else false. This applies to all three variants of the FOR statement (integer FOR loops, record-set FOR loops, and dynamic record-set FOR loops). FOUND is set this way when the FOR loop exits; inside the execution of the loop, FOUND is not modified by the FOR statement, although it might be changed by the execution of other statements within the loop body.

FOUND is a local variable within each PL/pgSQL function; any changes to it affect only the current function.
38.5.6. Doing Nothing At All

Sometimes a placeholder statement that does nothing is useful. For example, it can indicate that one arm of an if/then/else chain is deliberately empty. For this purpose, use the `NULL` statement:

```
NULL;
```

For example, the following two fragments of code are equivalent:

```
BEGIN
  y := x / 0;
EXCEPTION
  WHEN division_by_zero THEN
    NULL; -- ignore the error
END;

BEGIN
  y := x / 0;
EXCEPTION
  WHEN division_by_zero THEN -- ignore the error
END;
```

Which is preferable is a matter of taste.

**Note:** In Oracle’s PL/SQL, empty statement lists are not allowed, and so `NULL` statements are *required* for situations such as this. PL/pgSQL allows you to just write nothing, instead.

38.6. Control Structures

Control structures are probably the most useful (and important) part of PL/pgSQL. With PL/pgSQL’s control structures, you can manipulate PostgreSQL data in a very flexible and powerful way.

38.6.1. Returning From a Function

There are two commands available that allow you to return data from a function: `RETURN` and `RETURN NEXT`.

38.6.1.1. RETURN

```
RETURN expression;
```

`RETURN` with an expression terminates the function and returns the value of `expression` to the caller. This form is to be used for PL/pgSQL functions that do not return a set.

When returning a scalar type, any expression can be used. The expression’s result will be automatically cast into the function’s return type as described for assignments. To return a composite (row) value, you must write a record or row variable as the `expression`. 
Chapter 38. PL/pgSQL - SQL Procedural Language

If you declared the function with output parameters, write just `RETURN` with no expression. The current values of the output parameter variables will be returned.

If you declared the function to return `void`, a `RETURN` statement can be used to exit the function early; but do not write an expression following `RETURN`.

The return value of a function cannot be left undefined. If control reaches the end of the top-level block of the function without hitting a `RETURN` statement, a run-time error will occur. This restriction does not apply to functions with output parameters and functions returning `void`, however. In those cases a `RETURN` statement is automatically executed if the top-level block finishes.

### 38.6.1.2. RETURN NEXT and RETURN QUERY

```sql
RETURN NEXT expression;
RETURN QUERY query;
```

When a PL/pgSQL function is declared to return `SETOF sometype`, the procedure to follow is slightly different. In that case, the individual items to return are specified by a sequence of `RETURN NEXT` or `RETURN QUERY` commands, and then a final `RETURN` command with no argument is used to indicate that the function has finished executing. `RETURN NEXT` can be used with both scalar and composite data types; with a composite result type, an entire “table” of results will be returned. `RETURN QUERY` appends the results of executing a query to the function’s result set. `RETURN NEXT` and `RETURN QUERY` can be freely intermixed in a single set-returning function, in which case their results will be concatenated.

`RETURN NEXT` and `RETURN QUERY` do not actually return from the function — they simply append zero or more rows to the function’s result set. Execution then continues with the next statement in the PL/pgSQL function. As successive `RETURN NEXT` or `RETURN QUERY` commands are executed, the result set is built up. A final `RETURN`, which should have no argument, causes control to exit the function (or you can just let control reach the end of the function).

If you declared the function with output parameters, write just `RETURN NEXT` with no expression. On each execution, the current values of the output parameter variable(s) will be saved for eventual return as a row of the result. Note that you must declare the function as returning `SETOF record` when there are multiple output parameters, or `SETOF sometype` when there is just one output parameter of type `sometype`, in order to create a set-returning function with output parameters.

Here is an example of a function using `RETURN NEXT`:

```sql
CREATE TABLE foo (fooid INT, foosubid INT, fooname TEXT);
INSERT INTO foo VALUES (1, 2, 'three');
INSERT INTO foo VALUES (4, 5, 'six');

CREATE OR REPLACE FUNCTION getAllFoo() RETURNS SETOF foo AS $BODY$
DECLARE
  r foo%rowtype;
BEGIN
  FOR r IN SELECT * FROM foo
  WHERE fooid > 0
  LOOP
    -- can do some processing here
    RETURN NEXT r; -- return current row of SELECT
  END LOOP;
RETURN;
END
$BODY$
```

---

...
Chapter 38. PL/pgSQL - SQL Procedural Language

Note that functions using `RETURN NEXT` or `RETURN QUERY` must be called as a table source in a `FROM` clause.

Note: The current implementation of `RETURN NEXT` and `RETURN QUERY` stores the entire result set before returning from the function, as discussed above. That means that if a PL/pgSQL function produces a very large result set, performance might be poor: data will be written to disk to avoid memory exhaustion, but the function itself will not return until the entire result set has been generated. A future version of PL/pgSQL might allow users to define set-returning functions that do not have this limitation. Currently, the point at which data begins being written to disk is controlled by the `work_mem` configuration variable. Administrators who have sufficient memory to store larger result sets in memory should consider increasing this parameter.

38.6.2. Conditionals

`IF` statements let you execute commands based on certain conditions. PL/pgSQL has five forms of `IF`:

• `IF ... THEN`
• `IF ... THEN ... ELSE`
• `IF ... THEN ... ELSE IF`
• `IF ... THEN ... ELSIF ... THEN ... ELSE`
• `IF ... THEN ... ELSEIF ... THEN ... ELSE`

38.6.2.1. IF–THEN

`IF `boolean-expression` THEN
  statements
END IF;`

IF–THEN statements are the simplest form of `IF`. The statements between `THEN` and `END IF` will be executed if the condition is true. Otherwise, they are skipped.

Example:

```sql
IF v_user_id <> 0 THEN
  UPDATE users SET email = v_email WHERE user_id = v_user_id;
END IF;
```
38.6.2.2. IF-THEN-ELSE

IF boolean-expression THEN
    statements
ELSE
    statements
END IF;

IF-THEN-ELSE statements add to IF-THEN by letting you specify an alternative set of statements that should be executed if the condition evaluates to false.

Examples:

IF parentid IS NULL OR parentid = "" THEN
    RETURN fullname;
ELSE
    RETURN hp_true_filename(parentid) || '/' || fullname;
END IF;

IF v_count > 0 THEN
    INSERT INTO users_count (count) VALUES (v_count);
    RETURN 't';
ELSE
    RETURN 'f';
END IF;

38.6.2.3. IF-THEN-ELSE IF

IF statements can be nested, as in the following example:

IF demo_row.sex = 'm' THEN
    prettySex := 'man';
ELSE
    IF demo_row.sex = 'f' THEN
        prettySex := 'woman';
    END IF;
END IF;

When you use this form, you are actually nesting an IF statement inside the ELSE part of an outer IF statement. Thus you need one END IF statement for each nested IF and one for the parent IF-ELSE. This is workable but grows tedious when there are many alternatives to be checked. Hence the next form.

38.6.2.4. IF-THEN-ELSIF-ELSE

IF boolean-expression THEN
    statements
[ ELSIF boolean-expression THEN
    statements
[ ELSIF boolean-expression THEN
    statements

IF-THEN-ELSEIF-ELSE provides a more convenient method of checking many alternatives in one statement. Functionally it is equivalent to nested IF-THEN-ELSE-IF-THEN commands, but only one END IF is needed.

Here is an example:

```
IF number = 0 THEN
    result := 'zero';
ELSIF number > 0 THEN
    result := 'positive';
ELSIF number < 0 THEN
    result := 'negative';
ELSE
    -- hmm, the only other possibility is that number is null
    result := 'NULL';
END IF;
```

38.6.2.5. IF-THEN-ELSEIF-ELSE

ELSEIF is an alias for ELSIF.

38.6.3. Simple Loops

With the LOOP, EXIT, CONTINUE, WHILE, and FOR statements, you can arrange for your PL/pgSQL function to repeat a series of commands.

38.6.3.1. LOOP

```
[ <<<label>>> ]
LOOP
    statements
END LOOP [ label ];
```

LOOP defines an unconditional loop that is repeated indefinitely until terminated by an EXIT or RETURN statement. The optional label can be used by EXIT and CONTINUE statements in nested loops to specify which loop the statement should be applied to.

38.6.3.2. EXIT

```
EXIT [ label ] [ WHEN boolean-expression ];
```

If no label is given, the innermost loop is terminated and the statement following END LOOP is executed next. If label is given, it must be the label of the current or some outer level of nested loop.
or block. Then the named loop or block is terminated and control continues with the statement after the loop's/block's corresponding END.

If WHEN is specified, the loop exit occurs only if boolean-expression is true. Otherwise, control passes to the statement after EXIT.

EXIT can be used with all types of loops; it is not limited to use with unconditional loops. When used with a BEGIN block, EXIT passes control to the next statement after the end of the block.

Examples:

```sql
LOOP
  -- some computations
  IF count > 0 THEN
    EXIT;  -- exit loop
  END IF;
END LOOP;

LOOP
  -- some computations
  EXIT WHEN count > 0;  -- same result as previous example
END LOOP;

BEGIN
  -- some computations
  IF stocks > 100000 THEN
    EXIT;  -- causes exit from the BEGIN block
  END IF;
END;
```

38.6.3.3. CONTINUE

CONTINUE [ label ] [ WHEN boolean-expression ];

If no label is given, the next iteration of the innermost loop is begun. That is, all statements remaining in the loop body are skipped, and control returns to the loop control expression (if any) to determine whether another loop iteration is needed. If label is present, it specifies the label of the loop whose execution will be continued.

If WHEN is specified, the next iteration of the loop is begun only if boolean-expression is true. Otherwise, control passes to the statement after CONTINUE.

CONTINUE can be used with all types of loops; it is not limited to use with unconditional loops.

Examples:

```sql
LOOP
  -- some computations
  EXIT WHEN count > 100;
  CONTINUE WHEN count < 50;
  -- some computations for count IN [50 .. 100]
END LOOP;
```
### 38.6.3.4. WHILE

```sql
[ <<{label}>> ]
WHILE boolean-expression LOOP
  statements
END LOOP [ {label} ];
```

The **WHILE** statement repeats a sequence of statements so long as the `boolean-expression` evaluates to true. The expression is checked just before each entry to the loop body.

For example:

```sql
WHILE amount_owed > 0 AND gift_certificate_balance > 0 LOOP
  -- some computations here
END LOOP;
WHILE NOT done LOOP
  -- some computations here
END LOOP;
```

### 38.6.3.5. FOR (integer variant)

```sql
[ <<{label}>> ]
FOR name IN [ REVERSE ] expression .. expression [ BY expression ] LOOP
  statements
END LOOP [ {label} ];
```

This form of **FOR** creates a loop that iterates over a range of integer values. The variable `name` is automatically defined as type `integer` and exists only inside the loop (any existing definition of the variable name is ignored within the loop). The two expressions giving the lower and upper bound of the range are evaluated once when entering the loop. If the `BY` clause isn’t specified the iteration step is 1, otherwise it’s the value specified in the `BY` clause, which again is evaluated once on loop entry.

If `REVERSE` is specified then the step value is subtracted, rather than added, after each iteration.

Some examples of integer **FOR** loops:

```sql
FOR i IN 1..10 LOOP
  -- i will take on the values 1,2,3,4,5,6,7,8,9,10 within the loop
END LOOP;
FOR i IN REVERSE 10..1 LOOP
  -- i will take on the values 10,9,8,7,6,5,4,3,2,1 within the loop
END LOOP;
FOR i IN REVERSE 10..1 BY 2 LOOP
  -- i will take on the values 10,8,6,4,2 within the loop
END LOOP;
```

If the lower bound is greater than the upper bound (or less than, in the `REVERSE` case), the loop body is not executed at all. No error is raised.

If a `label` is attached to the **FOR** loop then the integer loop variable can be referenced with a qualified name, using that `label`. 

742
### 38.6.4. Looping Through Query Results

Using a different type of `FOR` loop, you can iterate through the results of a query and manipulate that data accordingly. The syntax is:

```sql
[ <<label>> ]
FOR target IN query LOOP
    statements
END LOOP [ label ];
```

The `target` is a record variable, row variable, or comma-separated list of scalar variables. The `target` is successively assigned each row resulting from the `query` and the loop body is executed for each row. Here is an example:

```sql
CREATE FUNCTION cs_refresh_mviews() RETURNS integer AS $$
DECLARE
    mviews RECORD;
BEGIN
    PERFORM cs_log('Refreshing materialized views...');
    FOR mviews IN SELECT * FROM cs_materialized_views ORDER BY sort_key LOOP
        -- Now "mviews" has one record from cs_materialized_views
        PERFORM cs_log('Refreshing materialized view ' || quote_ident(mviews.mv_name) || ' ...');
        EXECUTE 'TRUNCATE TABLE ' || quote_ident(mviews.mv_name);
        EXECUTE 'INSERT INTO ' || quote_ident(mviews.mv_name) || ' ' || mviews.mv_query;
    END LOOP;
    PERFORM cs_log('Done refreshing materialized views.');
    RETURN 1;
END;
$$ LANGUAGE plpgsql;
```

If the loop is terminated by an `EXIT` statement, the last assigned row value is still accessible after the loop.

The `query` used in this type of `FOR` statement can be any SQL command that returns rows to the caller: `SELECT` is the most common case, but you can also use `INSERT`, `UPDATE`, or `DELETE` with a `RETURNING` clause. Some utility commands such as `EXPLAIN` will work too.

`PL/pgSQL` variables are substituted into the query text, and the query plan is cached for possible re-use, as discussed in detail in Section 38.10.1 and Section 38.10.2.

The `FOR-IN-EXECUTE` statement is another way to iterate over rows:

```sql
[ <<label>> ]
FOR target IN EXECUTE text_expression LOOP
    statements
END LOOP [ label ];
```

This is like the previous form, except that the source query is specified as a string expression, which is evaluated and replanned on each entry to the `FOR` loop. This allows the programmer to choose the speed of a preplanned query or the flexibility of a dynamic query, just as with a plain `EXECUTE` statement.
38.6.5. Trapping Errors

By default, any error occurring in a PL/pgSQL function aborts execution of the function, and indeed of the surrounding transaction as well. You can trap errors and recover from them by using a `BEGIN` block with an `EXCEPTION` clause. The syntax is an extension of the normal syntax for a `BEGIN` block:

```sql
[ <<label>> ]
[ DECLARE declarations ]
BEGIN
  statements
EXCEPTION
  WHEN condition [ OR condition ... ] THEN
    handler_statements
  [ WHEN condition [ OR condition ... ] THEN
    handler_statements
  ... ]
END;
```

If no error occurs, this form of block simply executes all the `statements`, and then control passes to the next statement after `END`. But if an error occurs within the `statements`, further processing of the `statements` is abandoned, and control passes to the `EXCEPTION` list. The list is searched for the first `condition` matching the error that occurred. If a match is found, the corresponding `handler_statements` are executed, and then control passes to the next statement after `END`. If no match is found, the error propagates out as though the `EXCEPTION` clause were not there at all: the error can be caught by an enclosing block with `EXCEPTION`, or if there is none it aborts processing of the function.

The `condition` names can be any of those shown in Appendix A. A category name matches any error within its category. The special condition name `OTHERS` matches every error type except `QUERY_CANCELED`. (It is possible, but often unwise, to trap `QUERY_CANCELED` by name.) Condition names are not case-sensitive.

If a new error occurs within the selected `handler_statements`, it cannot be caught by this `EXCEPTION` clause, but is propagated out. A surrounding `EXCEPTION` clause could catch it.

When an error is caught by an `EXCEPTION` clause, the local variables of the PL/pgSQL function remain as they were when the error occurred, but all changes to persistent database state within the block are rolled back. As an example, consider this fragment:

```sql
INSERT INTO mytab(firstname, lastname) VALUES('Tom', 'Jones');
BEGIN
  UPDATE mytab SET firstname = 'Joe' WHERE lastname = 'Jones';
  x := x + 1;
  y := x / 0;
EXCEPTION
  WHEN division_by_zero THEN
    RAISE NOTICE 'caught division_by_zero';
    RETURN x;
END;
```

When control reaches the assignment to `y`, it will fail with a `division_by_zero` error. This will be caught by the `EXCEPTION` clause. The value returned in the `RETURN` statement will be the incremented value of `x`, but the effects of the `UPDATE` command will have been rolled back. The `INSERT` command preceding the block is not rolled back, however, so the end result is that the database contains Tom Jones not Joe Jones.
Tip: A block containing an `EXCEPTION` clause is significantly more expensive to enter and exit than a block without one. Therefore, don’t use `EXCEPTION` without need.

Within an exception handler, the `SQLSTATE` variable contains the error code that corresponds to the exception that was raised (refer to Table A-1 for a list of possible error codes). The `SQLERRM` variable contains the error message associated with the exception. These variables are undefined outside exception handlers.

Example 38-1. Exceptions with `UPDATE/INSERT`

This example uses exception handling to perform either `UPDATE` or `INSERT`, as appropriate:

```sql
CREATE TABLE db (a INT PRIMARY KEY, b TEXT);
CREATE FUNCTION merge_db(key INT, data TEXT) RETURNS VOID AS $$
BEGIN
  LOOP
    -- first try to update the key
    UPDATE db SET b = data WHERE a = key;
    IF found THEN
      RETURN;
    END IF;
    -- not there, so try to insert the key
    -- if someone else inserts the same key concurrently,
    -- we could get a unique-key failure
    BEGIN
      INSERT INTO db(a,b) VALUES (key, data);
      RETURN;
    EXCEPTION WHEN unique_violation THEN
      -- do nothing, and loop to try the UPDATE again
    END;
  END LOOP;
END;
$$ LANGUAGE plpgsql;

SELECT merge_db(1, 'david');
SELECT merge_db(1, 'dennis');
```

38.7. Cursors

Rather than executing a whole query at once, it is possible to set up a cursor that encapsulates the query, and then read the query result a few rows at a time. One reason for doing this is to avoid memory overrun when the result contains a large number of rows. (However, PL/pgSQL users do not normally need to worry about that, since `FOR` loops automatically use a cursor internally to avoid memory problems.) A more interesting usage is to return a reference to a cursor that a function has created, allowing the caller to read the rows. This provides an efficient way to return large row sets from functions.
38.7.1. Declaring Cursor Variables

All access to cursors in PL/pgSQL goes through cursor variables, which are always of the special data type refcursor. One way to create a cursor variable is just to declare it as a variable of type refcursor. Another way is to use the cursor declaration syntax, which in general is:

```
name [ [ NO ] SCROLL ] CURSOR [ ( arguments ) ] FOR query;
```

(for can be replaced by IS for Oracle compatibility.) If SCROLL is specified, the cursor will be capable of scrolling backward; if NO SCROLL is specified, backward fetches will be rejected; if neither specification appears, it is query-dependent whether backward fetches will be allowed. arguments, if specified, is a comma-separated list of pairs name datatype that define names to be replaced by parameter values in the given query. The actual values to substitute for these names will be specified later, when the cursor is opened.

Some examples:

```
DECLARE
    curs1 refcursor;
    curs2 CURSOR FOR SELECT * FROM tenk1;
    curs3 CURSOR (key integer) IS SELECT * FROM tenk1 WHERE unique1 = key;
```

All three of these variables have the data type refcursor, but the first can be used with any query, while the second has a fully specified query already bound to it, and the last has a parameterized query bound to it. (key will be replaced by an integer parameter value when the cursor is opened.) The variable curs1 is said to be unbound since it is not bound to any particular query.

38.7.2. Opening Cursors

Before a cursor can be used to retrieve rows, it must be opened. (This is the equivalent action to the SQL command DECLARE CURSOR.) PL/pgSQL has three forms of the OPEN statement, two of which use unbound cursor variables while the third uses a bound cursor variable.

38.7.2.1. OPEN FOR query

```
OPEN unbound_cursor [ [ NO ] SCROLL ] FOR query;
```

The cursor variable is opened and given the specified query to execute. The cursor cannot be open already, and it must have been declared as an unbound cursor (that is, as a simple refcursor variable). The query must be a SELECT, or something else that returns rows (such as EXPLAIN). The query is treated in the same way as other SQL commands in PL/pgSQL: PL/pgSQL variable names are substituted, and the query plan is cached for possible reuse. When a PL/pgSQL variable is substituted into the cursor query, the value that is substituted is the one it has at the time of the OPEN; subsequent changes to the variable will not affect the cursor’s behavior. The SCROLL and NO SCROLL options have the same meanings as for a bound cursor.

An example:

```
OPEN curs1 FOR SELECT * FROM foo WHERE key = mykey;
```
38.7.2.2. OPEN FOR EXECUTE

OPEN unbound_cursor [ [ NO ] SCROLL ] FOR EXECUTE query_string;

The cursor variable is opened and given the specified query to execute. The cursor cannot be open already, and it must have been declared as an unbound cursor (that is, as a simple refcursor variable). The query is specified as a string expression, in the same way as in the EXECUTE command. As usual, this gives flexibility so the query plan can vary from one run to the next (see Section 38.10.2), and it also means that variable substitution is not done on the command string. The SCROLL and NO SCROLL options have the same meanings as for a bound cursor.

An example:

OPEN curs1 FOR EXECUTE 'SELECT * FROM ' || quote_ident($1);

38.7.2.3. Opening a Bound Cursor

OPEN bound_cursor [ ( argument_values ) ];

This form of OPEN is used to open a cursor variable whose query was bound to it when it was declared. The cursor cannot be open already. A list of actual argument value expressions must appear if and only if the cursor was declared to take arguments. These values will be substituted in the query. The query plan for a bound cursor is always considered cacheable; there is no equivalent of EXECUTE in this case. Notice that SCROLL and NO SCROLL cannot be specified, as the cursor’s scrolling behavior was already determined.

Note that because variable substitution is done on the bound cursor’s query, there are two ways to pass values into the cursor: either with an explicit argument to OPEN, or implicitly by referencing a PL/pgSQL variable in the query. However, only variables declared before the bound cursor was declared will be substituted into it. In either case the value to be passed is determined at the time of the OPEN.

Examples:

OPEN curs2;
OPEN curs3(42);

38.7.3. Using Cursors

Once a cursor has been opened, it can be manipulated with the statements described here.

These manipulations need not occur in the same function that opened the cursor to begin with. You can return a refcursor value out of a function and let the caller operate on the cursor. (Internally, a refcursor value is simply the string name of a so-called portal containing the active query for the cursor. This name can be passed around, assigned to other refcursor variables, and so on, without disturbing the portal.)

All portals are implicitly closed at transaction end. Therefore a refcursor value is usable to reference an open cursor only until the end of the transaction.
38.7.3.1. FETCH

FETCH [ direction { FROM | IN } ] cursor INTO target;

FETCH retrieves the next row from the cursor into a target, which might be a row variable, a record variable, or a comma-separated list of simple variables, just like SELECT INTO. If there is no next row, the target is set to NULL(s). As with SELECT INTO, the special variable FOUND can be checked to see whether a row was obtained or not.

The direction clause can be any of the variants allowed in the SQL FETCH command except the ones that can fetch more than one row; namely, it can be NEXT, PRIOR, FIRST, LAST, ABSOLUTE count, RELATIVE count, FORWARD, or BACKWARD. Omitting direction is the same as specifying NEXT. direction values that require moving backward are likely to fail unless the cursor was declared or opened with the SCROLL option.

cursor must be the name of a refcursor variable that references an open cursor portal.

Examples:

FETCH curs1 INTO rowvar;
FETCH curs2 INTO foo, bar, baz;
FETCH LAST FROM curs3 INTO x, y;
FETCH RELATIVE -2 FROM curs4 INTO x;

38.7.3.2. MOVE

MOVE [ direction { FROM | IN } ] cursor;

MOVE repositions a cursor without retrieving any data. MOVE works exactly like the FETCH command, except it only repositions the cursor and does not return the row moved to. As with SELECT INTO, the special variable FOUND can be checked to see whether there was a next row to move to.

The options for the direction clause are the same as for FETCH, namely NEXT, PRIOR, FIRST, LAST, ABSOLUTE count, RELATIVE count, FORWARD, or BACKWARD. Omitting direction is the same as specifying NEXT. direction values that require moving backward are likely to fail unless the cursor was declared or opened with the SCROLL option.

Examples:

MOVE curs1;
MOVE LAST FROM curs3;
MOVE RELATIVE -2 FROM curs4;

38.7.3.3. UPDATE/DELETE WHERE CURRENT OF

UPDATE table SET ... WHERE CURRENT OF cursor;
DELETE FROM table WHERE CURRENT OF cursor;

When a cursor is positioned on a table row, that row can be updated or deleted using the cursor to identify the row. Note that this only works for simple (non-join, non-grouping) cursor queries. For additional information see the DECLARE reference page.
An example:

```
UPDATE foo SET dataval = myval WHERE CURRENT OF curs1;
```

### 38.7.3.4. close

```
CLOSE cursor;
```

CLOSE closes the portal underlying an open cursor. This can be used to release resources earlier than end of transaction, or to free up the cursor variable to be opened again.

An example:

```
CLOSE curs1;
```

### 38.7.3.5. Returning Cursors

PL/pgSQL functions can return cursors to the caller. This is useful to return multiple rows or columns, especially with very large result sets. To do this, the function opens the cursor and returns the cursor name to the caller (or simply opens the cursor using a portal name specified by or otherwise known to the caller). The caller can then fetch rows from the cursor. The cursor can be closed by the caller, or it will be closed automatically when the transaction closes.

The portal name used for a cursor can be specified by the programmer or automatically generated. To specify a portal name, simply assign a string to the `refcursor` variable before opening it. The string value of the `refcursor` variable will be used by `OPEN` as the name of the underlying portal. However, if the `refcursor` variable is null, `OPEN` automatically generates a name that does not conflict with any existing portal, and assigns it to the `refcursor` variable.

**Note:** A bound cursor variable is initialized to the string value representing its name, so that the portal name is the same as the cursor variable name, unless the programmer overrides it by assignment before opening the cursor. But an unbound cursor variable defaults to the null value initially, so it will receive an automatically-generated unique name, unless overridden.

The following example shows one way a cursor name can be supplied by the caller:

```
CREATE TABLE test (col text);
INSERT INTO test VALUES ('123');

CREATE FUNCTION reffunc(refcursor) RETURNS refcursor AS 'BEGIN
    OPEN $1 FOR SELECT col FROM test;
    RETURN $1;
END;
' LANGUAGE plpgsql;

BEGIN;
SELECT reffunc('funcursor');
FETCH ALL IN funcursor;
```
The following example uses automatic cursor name generation:

```sql
CREATE FUNCTION reffunc2() RETURNS refcursor AS '
DECLARE
    ref refcursor;
BEGIN
    OPEN ref FOR SELECT col FROM test;
    RETURN ref;
END;
' LANGUAGE plpgsql;

BEGIN;
SELECT reffunc2();

reffunc2
-------------------
<unnamed cursor 1>
(1 row)

FETCH ALL IN "<unnamed cursor 1>";
COMMIT;

The following example shows one way to return multiple cursors from a single function:

```sql
CREATE FUNCTION myfunc(refcursor, refcursor) RETURNS SETOF refcursor AS $$
BEGIN
    OPEN $1 FOR SELECT * FROM table_1;
    RETURN NEXT $1;
    OPEN $2 FOR SELECT * FROM table_2;
    RETURN NEXT $2;
END;
$$ LANGUAGE plpgsql;

-- need to be in a transaction to use cursors.
BEGIN;
SELECT * FROM myfunc('a', 'b');

FETCH ALL FROM a;
FETCH ALL FROM b;
COMMIT;
```
38.8. Errors and Messages

Use the RAISE statement to report messages and raise errors.

RAISE level 'format' [, expression [, ...]];

Possible levels are DEBUG, LOG, INFO, NOTICE, WARNING, and EXCEPTION. EXCEPTION raises an error (which normally aborts the current transaction); the other levels only generate messages of different priority levels. Whether messages of a particular priority are reported to the client, written to the server log, or both is controlled by the log_min_messages and client_min_messages configuration variables. See Chapter 18 for more information.

Inside the format string, % is replaced by the next optional argument’s string representation. Write %% to emit a literal %. Arguments can be simple variables or expressions, but the format must be a simple string literal.

In this example, the value of v_job_id will replace the % in the string:

RAISE NOTICE 'Calling cs_create_job(%)', v_job_id;

This example will abort the transaction with the given error message:

RAISE EXCEPTION 'Nonexistent ID --> %', user_id;

RAISE EXCEPTION presently always generates the same SQLSTATE code, P0001, no matter what message it is invoked with. It is possible to trap this exception with EXCEPTION ... WHEN RAISE_EXCEPTION THEN ... but there is no way to tell one RAISE from another.

38.9. Trigger Procedures

PL/pgSQL can be used to define trigger procedures. A trigger procedure is created with the CREATE FUNCTION command, declaring it as a function with no arguments and a return type of trigger. Note that the function must be declared with no arguments even if it expects to receive arguments specified in CREATE TRIGGER — trigger arguments are passed via TG_ARGV, as described below.

When a PL/pgSQL function is called as a trigger, several special variables are created automatically in the top-level block. They are:

NEW

Data type RECORD; variable holding the new database row for INSERT/UPDATE operations in row-level triggers. This variable is NULL in statement-level triggers.

OLD

Data type RECORD; variable holding the old database row for UPDATE/DELETE operations in row-level triggers. This variable is NULL in statement-level triggers.

TG_NAME

Data type name; variable that contains the name of the trigger actually fired.

TG_WHEN

Data type text; a string of either BEFORE or AFTER depending on the trigger’s definition.
TG_LEVEL
Data type text; a string of either ROW or STATEMENT depending on the trigger’s definition.

TG_OP
Data type text; a string of INSERT, UPDATE, or DELETE telling for which operation the trigger was fired.

TG_RELID
Data type oid; the object ID of the table that caused the trigger invocation.

TG_RELNAME
Data type name; the name of the table that caused the trigger invocation. This is now deprecated, and could disappear in a future release. Use TG_TABLE_NAME instead.

TG_TABLE_NAME
Data type name; the name of the table that caused the trigger invocation.

TG_TABLE_SCHEMA
Data type name; the name of the schema of the table that caused the trigger invocation.

TG_NARGS
Data type integer; the number of arguments given to the trigger procedure in the CREATE TRIGGER statement.

TG_ARGV[]
Data type array of text; the arguments from the CREATE TRIGGER statement. The index counts from 0. Invalid indices (less than 0 or greater than or equal to tg_nargs) result in a null value.

A trigger function must return either NULL or a record/row value having exactly the structure of the table the trigger was fired for.

Row-level triggers fired BEFORE can return null to signal the trigger manager to skip the rest of the operation for this row (i.e., subsequent triggers are not fired, and the INSERT/UPDATE/DELETE does not occur for this row). If a nonnull value is returned then the operation proceeds with that row value. Returning a row value different from the original value of NEW alters the row that will be inserted or updated (but has no direct effect in the DELETE case). To alter the row to be stored, it is possible to replace single values directly in NEW and return the modified NEW, or to build a complete new record/row to return.

The return value of a BEFORE or AFTER statement-level trigger or an AFTER row-level trigger is always ignored; it might as well be null. However, any of these types of triggers might still abort the entire operation by raising an error.

Example 38-2 shows an example of a trigger procedure in PL/pgSQL.

**Example 38-2. A PL/pgSQL Trigger Procedure**

This example trigger ensures that any time a row is inserted or updated in the table, the current user name and time are stamped into the row. And it checks that an employee’s name is given and that the salary is a positive value.

```sql
CREATE TABLE emp (  
    empname text,  
    salary integer,  
    last_date timestamp,
```
Chapter 38. PL/pgSQL - SQL Procedural Language

last_user text
);

CREATE FUNCTION emp_stamp() RETURNS trigger AS $emp_stamp$
BEGIN
  -- Check that empname and salary are given
  IF NEW.empname IS NULL THEN
    RAISE EXCEPTION 'empname cannot be null';
  END IF;
  IF NEW.salary IS NULL THEN
    RAISE EXCEPTION '% cannot have null salary', NEW.empname;
  END IF;

  -- Who works for us when she must pay for it?
  IF NEW.salary < 0 THEN
    RAISE EXCEPTION '% cannot have a negative salary', NEW.empname;
  END IF;

  -- Remember who changed the payroll when
  NEW.last_date := current_timestamp;
  NEW.last_user := current_user;
  RETURN NEW;
END;
$emp_stamp$ LANGUAGE plpgsql;

CREATE TRIGGER emp_stamp BEFORE INSERT OR UPDATE ON emp
  FOR EACH ROW EXECUTE PROCEDURE emp_stamp();

Another way to log changes to a table involves creating a new table that holds a row for each insert, update, or delete that occurs. This approach can be thought of as auditing changes to a table. Example 38-3 shows an example of an audit trigger procedure in PL/pgSQL.

Example 38-3. A PL/pgSQL Trigger Procedure For Auditing

This example trigger ensures that any insert, update or delete of a row in the emp table is recorded (i.e., audited) in the emp_audit table. The current time and user name are stamped into the row, together with the type of operation performed on it.

CREATE TABLE emp (
  empname text NOT NULL,
  salary integer
);

CREATE TABLE emp_audit(
  operation char(1) NOT NULL,
  stamp timestamp NOT NULL,
  userid text NOT NULL,
  empname text NOT NULL,
  salary integer
);

CREATE OR REPLACE FUNCTION process_emp_audit() RETURNS TRIGGER AS $emp_audit$
BEGIN
  -- Create a row in emp_audit to reflect the operation performed on emp,
  -- make use of the special variable TG_OP to work out the operation.
  --
Chapter 38. PL/pgSQL - SQL Procedural Language

IF (TG_OP = 'DELETE') THEN
    INSERT INTO emp_audit SELECT 'D', now(), user, OLD.*;
    RETURN OLD;
ELSIF (TG_OP = 'UPDATE') THEN
    INSERT INTO emp_audit SELECT 'U', now(), user, NEW.*;
    RETURN NEW;
ELSIF (TG_OP = 'INSERT') THEN
    INSERT INTO emp_audit SELECT 'I', now(), user, NEW.*;
    RETURN NEW;
END IF;
RETURN NULL; -- result is ignored since this is an AFTER trigger
END;

$emp_audit$ LANGUAGE plpgsql;

CREATE TRIGGER emp_audit
AFTER INSERT OR UPDATE OR DELETE ON emp
    FOR EACH ROW EXECUTE PROCEDURE process_emp_audit();

One use of triggers is to maintain a summary table of another table. The resulting summary can be used in place of the original table for certain queries — often with vastly reduced run times. This technique is commonly used in Data Warehousing, where the tables of measured or observed data (called fact tables) might be extremely large. Example 38-4 shows an example of a trigger procedure in PL/pgSQL that maintains a summary table for a fact table in a data warehouse.

Example 38-4. A PL/pgSQL Trigger Procedure For Maintaining A Summary Table

The schema detailed here is partly based on the Grocery Store example from The Data Warehouse Toolkit by Ralph Kimball.

```
-- Main tables - time dimension and sales fact.
--
CREATE TABLE time_dimension (  
time_key integer NOT NULL,
day_of_week integer NOT NULL,
day_of_month integer NOT NULL,
month integer NOT NULL,
quarter integer NOT NULL,
year integer NOT NULL
);
CREATE UNIQUE INDEX time_dimension_key ON time_dimension(time_key);

CREATE TABLE sales_fact (  
time_key integer NOT NULL,
product_key integer NOT NULL,
store_key integer NOT NULL,
amount_sold numeric(12,2) NOT NULL,
units_sold integer NOT NULL,
amount_cost numeric(12,2) NOT NULL
);
CREATE INDEX sales_fact_time ON sales_fact(time_key);

-- Summary table - sales by time.
--
CREATE TABLE sales_summary_bytime (  
time_key integer NOT NULL,
```

```
CREATE UNINDEX sales_summary_bytime_key ON sales_summary_bytime(time_key);
--
-- Function and trigger to amend summarized column(s) on UPDATE, INSERT, DELETE.
--
CREATE OR REPLACE FUNCTION maint_sales_summary_bytime() RETURNS TRIGGER AS $maint_sales_summary_bytime$
DECLARE
    delta_time_key integer;
    delta_amount_sold numeric(15,2); 
    delta_units_sold numeric(12);
    delta_amount_cost numeric(15,2);
BEGIN
    -- Work out the increment/decrement amount(s).
    IF (TG_OP = 'DELETE') THEN
        delta_time_key = OLD.time_key;
        delta_amount_sold = -1 * OLD.amount_sold;
        delta_units_sold = -1 * OLD.units_sold;
        delta_amount_cost = -1 * OLD.amount_cost;
    ELSIF (TG_OP = 'UPDATE') THEN
        -- forbid updates that change the time_key -
        -- (probably not too onerous, as DELETE + INSERT is how most
        -- changes will be made).
        IF ( OLD.time_key != NEW.time_key) THEN
            RAISE EXCEPTION 'Update of time_key : % -> % not allowed', OLD.time_key, NEW.time_key;
        END IF;
        delta_time_key = OLD.time_key;
        delta_amount_sold = NEW.amount_sold - OLD.amount_sold;
        delta_units_sold = NEW.units_sold - OLD.units_sold;
        delta_amount_cost = NEW.amount_cost - OLD.amount_cost;
    ELSIF (TG_OP = 'INSERT') THEN
        delta_time_key = NEW.time_key;
        delta_amount_sold = NEW.amount_sold;
        delta_units_sold = NEW.units_sold;
        delta_amount_cost = NEW.amount_cost;
    END IF;

    -- Insert or update the summary row with the new values.
    <<insert_update>>
    LOOP
        UPDATE sales_summary_bytime
        SET amount_sold = amount_sold + delta_amount_sold,
            units_sold = units_sold + delta_units_sold,
            amount_cost = amount_cost + delta_amount_cost
        WHERE time_key = delta_time_key;

END IF;

END}$maint_sales_summary_bytime$;

755
EXIT insert_update WHEN found;

BEGIN
    INSERT INTO sales_summary_bytime (
        time_key,
        amount_sold,
        units_sold,
        amount_cost
    ) VALUES (
        delta_time_key,
        delta_amount_sold,
        delta_units_sold,
        delta_amount_cost
    );

EXIT insert_update;

EXCEPTION
    WHEN UNIQUE_VIOLATION THEN
        -- do nothing
END;
END LOOP insert_update;

RETURN NULL;

END;
$maint_sales_summary_bytime$ LANGUAGE plpgsql;

CREATE TRIGGER maint_sales_summary_bytime
AFTER INSERT OR UPDATE OR DELETE ON sales_fact
FOR EACH ROW EXECUTE PROCEDURE maint_sales_summary_bytime();

INSERT INTO sales_fact VALUES(1,1,1,10,3,15);
INSERT INTO sales_fact VALUES(1,2,1,20,5,35);
INSERT INTO sales_fact VALUES(2,2,1,40,15,135);
INSERT INTO sales_fact VALUES(2,3,1,10,1,13);
SELECT * FROM sales_summary_bytime;
DELETE FROM sales_fact WHERE product_key = 1;
SELECT * FROM sales_summary_bytime;
UPDATE sales_fact SET units_sold = units_sold * 2;
SELECT * FROM sales_summary_bytime;

38.10. PL/pgSQL Under the Hood

This section discusses some implementation details that are frequently important for PL/pgSQL users to know.
38.10.1. Variable Substitution

When PL/pgSQL prepares a SQL statement or expression for execution, any PL/pgSQL variable name appearing in the statement or expression is replaced by a parameter symbol, \$n. The current value of the variable is then provided as the value for the parameter whenever the statement or expression is executed. As an example, consider the function

```
CREATE FUNCTION logfunc(logtxt text) RETURNS void AS $$
    DECLARE
        curtime timestamp := now();
    BEGIN
        INSERT INTO logtable VALUES (logtxt, curtime);
    END;
$$ LANGUAGE plpgsql;
```

The `INSERT` statement will effectively be processed as

```
PREPARE statement_name(text, timestamp) AS
    INSERT INTO logtable VALUES ($1, $2);
```

followed on each execution by `EXECUTE` with the current actual values of the two variables. (Note: here we are speaking of the main SQL engine's `EXECUTE` command, not PL/pgSQL's `EXECUTE`.)

The substitution mechanism will replace any token that matches a known variable's name. This poses various traps for the unwary. For example, it is a bad idea to use a variable name that is the same as any table or column name that you need to reference in queries within the function, because what you think is a table or column name will still get replaced. In the above example, suppose that `logtable` has column names `logtxt` and `logtime`, and we try to write the `INSERT` as

```
    INSERT INTO logtable (logtxt, logtime) VALUES (logtxt, curtime);
```

This will be fed to the main SQL parser as

```
    INSERT INTO logtable ($1, logtime) VALUES ($1, $2);
```

resulting in a syntax error like this:

```
ERROR: syntax error at or near "$1"
LINE 1: INSERT INTO logtable ( $1 , logtime) VALUES ( $1 , $2 ) ^
QUERY: INSERT INTO logtable ( $1 , logtime) VALUES ( $1 , $2 )
CONTEXT: SQL statement in PL/PgSQL function "logfunc2" near line 5
```

This example is fairly easy to diagnose, since it leads to an obvious syntax error. Much nastier are cases where the substitution is syntactically permissible, since the only symptom may be misbehavior of the function. In one case, a user wrote something like this:

```
DECLARE
    val text;
    search_key integer;
BEGIN
    ...
    FOR val IN SELECT val FROM table WHERE key = search_key LOOP ...
```

and wondered why all his table entries seemed to be NULL. Of course what happened here was that the query became

```
DECLARE
    val text;
    search_key integer;
BEGIN
    ...
    FOR val IN SELECT $1 FROM table WHERE key = $1 LOOP ...
```
A commonly used coding rule for avoiding such traps is to use a different naming convention for PL/pgSQL variables than you use for table and column names. For example, if all your variables are named `v_something` while none of your table or column names start with `v_`, you’re pretty safe.

Another workaround is to use qualified (dotted) names for SQL entities. For instance we could safely have written the above example as

```sql
FOR val IN SELECT table.val FROM table WHERE key = search_key LOOP ...
```

because PL/pgSQL will not substitute a variable for a trailing component of a qualified name. However this solution does not work in every case — you can’t qualify a name in an `INSERT`’s column name list, for instance. Another point is that record and row variable names will be matched to the first components of qualified names, so a qualified SQL name is still vulnerable in some cases. In such cases choosing a non-conflicting variable name is the only way.

Another technique you can use is to attach a label to the block in which your variables are declared, and then qualify the variable names in your SQL commands (see Section 38.2). For example,

```plsql
DECLARE
  val text;
BEGIN
  ...
  UPDATE table SET col = pl.val WHERE ...
```

This is not in itself a solution to the problem of conflicts, since an unqualified name in a SQL command is still at risk of being interpreted the “wrong” way. But it is useful for clarifying the intent of potentially-ambiguous code.

Variable substitution does not happen in the command string given to `EXECUTE` or one of its variants. If you need to insert a varying value into such a command, do so as part of constructing the string value, as illustrated in Section 38.5.4.

Variable substitution currently works only in `SELECT`, `INSERT`, `UPDATE`, and `DELETE` commands, because the main SQL engine allows parameter symbols only in these commands. To use a non-constant name or value in other statement types (generically called utility statements), you must construct the utility statement as a string and `EXECUTE` it.

### 38.10.2. Plan Caching

The PL/pgSQL interpreter parses the function’s source text and produces an internal binary instruction tree the first time the function is called (within each session). The instruction tree fully translates the PL/pgSQL statement structure, but individual SQL expressions and SQL commands used in the function are not translated immediately.

As each expression and SQL command is first executed in the function, the PL/pgSQL interpreter creates a prepared execution plan (using the SPI manager’s `SPI_prepare` and `SPI_saveplan` functions). Subsequent visits to that expression or command reuse the prepared plan. Thus, a function with conditional code that contains many statements for which execution plans might be required will only prepare and save those plans that are really used during the lifetime of the database connection. This can substantially reduce the total amount of time required to parse and generate execution plans for the statements in a PL/pgSQL function. A disadvantage is that errors in a specific expression or
command cannot be detected until that part of the function is reached in execution. (Trivial syntax
errors will be detected during the initial parsing pass, but anything deeper will not be detected until
execution.)

Once PL/pgSQL has made an execution plan for a particular command in a function, it will reuse that
plan for the life of the database connection. This is usually a win for performance, but it can cause
some problems if you dynamically alter your database schema. For example:

```plaintext
CREATE FUNCTION populate() RETURNS integer AS $$
DECLARE
    -- declarations
BEGIN
    PERFORM my_function();
END;
$$ LANGUAGE plpgsql;
```

If you execute the above function, it will reference the OID for `my_function()` in the execution
plan produced for the `PERFORM` statement. Later, if you drop and recreate `my_function()`, then
`populate()` will not be able to find `my_function()` anymore. You would then have to start a
new database session so that `populate()` will be compiled afresh, before it will work again. You
can avoid this problem by using `CREATE OR REPLACE FUNCTION` when updating the definition of
`my_function`, since when a function is “replaced”, its OID is not changed.

**Note:** In PostgreSQL 8.3 and later, saved plans will be replaced whenever any schema changes
have occurred to any tables they reference. This eliminates one of the major disadvantages of
saved plans. However, there is no such mechanism for function references, and thus the above
example involving a reference to a deleted function is still valid.

Because PL/pgSQL saves execution plans in this way, SQL commands that appear directly in a
PL/pgSQL function must refer to the same tables and columns on every execution; that is, you cannot
use a parameter as the name of a table or column in an SQL command. To get around this restriction,
you can construct dynamic commands using the PL/pgSQL `EXECUTE` statement — at the price of
constructing a new execution plan on every execution.

Another important point is that the prepared plans are parameterized to allow the values of PL/pgSQL
variables to change from one use to the next, as discussed in detail above. Sometimes this means
that a plan is less efficient than it would be if generated for a specific variable value. As an example,
consider

```plaintext
SELECT * INTO myrec FROM dictionary WHERE word LIKE search_term;
```

where `search_term` is a PL/pgSQL variable. The cached plan for this query will never use an index
on `word`, since the planner cannot assume that the `LIKE` pattern will be left-anchored at run time.
To use an index the query must be planned with a specific constant `LIKE` pattern provided. This is
another situation where `EXECUTE` can be used to force a new plan to be generated for each execution.

The mutable nature of record variables presents another problem in this connection. When fields of
a record variable are used in expressions or statements, the data types of the fields must not change
from one call of the function to the next, since each expression will be planned using the data type
that is present when the expression is first reached. `EXECUTE` can be used to get around this problem
when necessary.

If the same function is used as a trigger for more than one table, PL/pgSQL prepares and caches
plans independently for each such table — that is, there is a cache for each trigger function and table
combination, not just for each function. This alleviates some of the problems with varying data types;
for instance, a trigger function will be able to work successfully with a column named `key` even if it happens to have different types in different tables.

Likewise, functions having polymorphic argument types have a separate plan cache for each combination of actual argument types they have been invoked for, so that data type differences do not cause unexpected failures.

Plan caching can sometimes have surprising effects on the interpretation of time-sensitive values. For example there is a difference between what these two functions do:

```sql
CREATE FUNCTION logfunc1(logtxt text) RETURNS void AS $$
    BEGIN
        INSERT INTO logtable VALUES (logtxt, 'now');
    END;
$$ LANGUAGE plpgsql;
```

and:

```sql
CREATE FUNCTION logfunc2(logtxt text) RETURNS void AS $$
    DECLARE
        curtime timestamp;
    BEGIN
        curtime := 'now';
        INSERT INTO logtable VALUES (logtxt, curtime);
    END;
$$ LANGUAGE plpgsql;
```

In the case of `logfunc1`, the PostgreSQL main parser knows when preparing the plan for the `INSERT` that the string `'now'` should be interpreted as `timestamp`, because the target column of `logtable` is of that type. Thus, `'now'` will be converted to a constant when the `INSERT` is planned, and then used in all invocations of `logfunc1` during the lifetime of the session. Needless to say, this isn’t what the programmer wanted.

In the case of `logfunc2`, the PostgreSQL main parser does not know what type `'now'` should become and therefore it returns a data value of type `text` containing the string `now`. During the ensuing assignment to the local variable `curtime`, the PL/pgSQL interpreter casts this string to the `timestamp` type by calling the `text_out` and `timestamp_in` functions for the conversion. So, the computed time stamp is updated on each execution as the programmer expects.

### 38.11. Tips for Developing in PL/pgSQL

One good way to develop in PL/pgSQL is to use the text editor of your choice to create your functions, and in another window, use `psql` to load and test those functions. If you are doing it this way, it is a good idea to write the function using `CREATE OR REPLACE FUNCTION`. That way you can just reload the file to update the function definition. For example:

```sql
CREATE OR REPLACE FUNCTION testfunc(integer) RETURNS integer AS $$
    ....
$$ LANGUAGE plpgsql;
```

While running `psql`, you can load or reload such a function definition file with:
and then immediately issue SQL commands to test the function.

Another good way to develop in PL/pgSQL is with a GUI database access tool that facilitates development in a procedural language. One example of such a tool is pgAdmin, although others exist. These tools often provide convenient features such as escaping single quotes and making it easier to recreate and debug functions.

### 38.11.1. Handling of Quotation Marks

The code of a PL/pgSQL function is specified in `CREATE FUNCTION` as a string literal. If you write the string literal in the ordinary way with surrounding single quotes, then any single quotes inside the function body must be doubled; likewise any backslashes must be doubled (assuming escape string syntax is used). Doubling quotes is at best tedious, and in more complicated cases the code can become downright incomprehensible, because you can easily find yourself needing half a dozen or more adjacent quote marks. It’s recommended that you instead write the function body as a “dollar-quoting” string literal (see Section 4.1.2.2). In the dollar-quoting approach, you never double any quote marks, but instead take care to choose a different dollar-quoting delimiter for each level of nesting you need. For example, you might write the `CREATE FUNCTION` command as:

```sql
CREATE OR REPLACE FUNCTION testfunc(integer) RETURNS integer AS $PROC$
    ....
$PROC$ LANGUAGE plpgsql;
```

Within this, you might use quote marks for simple literal strings in SQL commands and $$ to delimit fragments of SQL commands that you are assembling as strings. If you need to quote text that includes $$, you could use $Q$, and so on.

The following chart shows what you have to do when writing quote marks without dollar quoting. It might be useful when translating pre-dollar quoting code into something more comprehensible.

<table>
<thead>
<tr>
<th>Quotation Mark</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 quotation mark</td>
<td>To begin and end the function body, for example:</td>
</tr>
<tr>
<td></td>
<td><code>CREATE FUNCTION foo() RETURNS integer AS '.....' LANGUAGE plpgsql;</code> Anywhere within a single-quoted function body, quote marks must appear in pairs.</td>
</tr>
<tr>
<td>2 quotation marks</td>
<td>For string literals inside the function body, for example:</td>
</tr>
<tr>
<td></td>
<td><code>a_output := &quot;Blah&quot;; SELECT * FROM users WHERE f_name=&quot;foobar&quot;;</code> In the dollar-quoting approach, you’d just write:</td>
</tr>
<tr>
<td></td>
<td><code>a_output := 'Blah'; SELECT * FROM users WHERE f_name='foobar';</code> which is exactly what the PL/pgSQL parser would see in either case.</td>
</tr>
<tr>
<td>4 quotation marks</td>
<td>When you need a single quotation mark in a string constant inside the function body, for example:</td>
</tr>
<tr>
<td></td>
<td>`a_output := a_output</td>
</tr>
</tbody>
</table>
In the dollar-quoting approach, you’d write:

```sql
a_output := a_output || $$ AND name LIKE 'foobar' AND xyz$$
```

being careful that any dollar-quote delimiters around this are not just $$. 6 quotation marks

When a single quotation mark in a string inside the function body is adjacent to the end of that string constant, for example:

```sql
a_output := a_output || " AND name LIKE "'foobar'"
```

The value appended to `a_output` would then be: `AND name LIKE 'foobar'.`

In the dollar-quoting approach, this becomes:

```sql
a_output := a_output || $$ AND name LIKE 'foobar'$$
```

10 quotation marks

When you want two single quotation marks in a string constant (which accounts for 8 quotation marks) and this is adjacent to the end of that string constant (2 more). You will probably only need that if you are writing a function that generates other functions, as in Example 38-6. For example:

```sql
a_output := a_output || " if v_" ||
    referrer_keys.kind || " like """
    || referrer_keys.key_string || """
then return """ || referrer_keys.referrer_type
    || """; end if;"
```

The value of `a_output` would then be:

```sql
if v_... like "..." then return "..."; end if;
```

In the dollar-quoting approach, this becomes:

```sql
a_output := a_output || $$ if v_$$ || referrer_keys.kind || $$ like '$$
    || referrer_keys.key_string || $$'
then return $$ || referrer_keys.referrer_type
    || $$'; end if;$$;
```

where we assume we only need to put single quote marks into `a_output`, because it will be re-quoted before use.

### 38.12. Porting from Oracle PL/SQL

This section explains differences between PostgreSQL’s PL/pgSQL language and Oracle’s PL/SQL language, to help developers who port applications from Oracle® to PostgreSQL.

PL/pgSQL is similar to PL/SQL in many aspects. It is a block-structured, imperative language, and all variables have to be declared. Assignments, loops, conditionals are similar. The main differences you should keep in mind when porting from PL/SQL to PL/pgSQL are:

- There are no default values for parameters in PostgreSQL.
- You can overload function names in PostgreSQL. This is often used to work around the lack of default parameters.
- If a name used in a SQL command could be either a column name of a table or a reference to a variable of the function, PL/SQL treats it as a column name, while PL/pgSQL treats it as a variable name. It’s best to avoid such ambiguities in the first place, but if necessary you can fix them by properly qualifying the ambiguous name. (See Section 38.10.1.)
• No need for cursors in PL/pgSQL, just put the query in the FOR statement. (See Example 38-6.)
• In PostgreSQL the function body must be written as a string literal. Therefore you need to use dollar quoting or escape single quotes in the function body. (See Section 38.11.1.)
• Instead of packages, use schemas to organize your functions into groups.
• Since there are no packages, there are no package-level variables either. This is somewhat annoying. You can keep per-session state in temporary tables instead.
• Integer FOR loops with REVERSE work differently: PL/SQL counts down from the second number to the first, while PL/pgSQL counts down from the first number to the second, requiring the loop bounds to be swapped when porting. This incompatibility is unfortunate but is unlikely to be changed. (See Section 38.6.3.5.)

38.12.1. Porting Examples

Example 38-5 shows how to port a simple function from PL/SQL to PL/pgSQL.

Example 38-5. Porting a Simple Function from PL/SQL to PL/pgSQL

Here is an Oracle PL/SQL function:

```sql
CREATE OR REPLACE FUNCTION cs_fmt_browser_version(v_name varchar,
v_version varchar)
RETURN varchar IS
BEGIN
  IF v_version IS NULL THEN
    RETURN v_name;
  END IF;
  RETURN v_name || '/' || v_version;
END;
/
```

Let’s go through this function and see the differences compared to PL/pgSQL:

• The RETURN key word in the function prototype (not the function body) becomes RETURNS in PostgreSQL. Also, IS becomes AS, and you need to add a LANGUAGE clause because PL/pgSQL is not the only possible function language.
• In PostgreSQL, the function body is considered to be a string literal, so you need to use quote marks or dollar quotes around it. This substitutes for the terminating / in the Oracle approach.
• The show errors command does not exist in PostgreSQL, and is not needed since errors are reported automatically.

This is how this function would look when ported to PostgreSQL:

```sql
CREATE OR REPLACE FUNCTION cs_fmt_browser_version(v_name varchar,
v_version varchar)
RETURNS varchar AS $$
BEGIN
  IF v_version IS NULL THEN
    RETURN v_name;
  END IF;
  RETURN v_name || '/' || v_version;
$$
```

763
Example 38-6 shows how to port a function that creates another function and how to handle the ensuing quoting problems.

**Example 38-6. Porting a Function that Creates Another Function from PL/SQL to PL/pgSQL**

The following procedure grabs rows from a `SELECT` statement and builds a large function with the results in `IF` statements, for the sake of efficiency. Notice particularly the differences in the cursor and the `FOR` loop.

This is the Oracle version:

```sql
CREATE OR REPLACE PROCEDURE cs_update_referrer_type_proc IS
    CURSOR referrer_keys IS
        SELECT * FROM cs_referrer_keys
        ORDER BY try_order;
    func_cmd VARCHAR(4000);
BEGIN
    func_cmd := 'CREATE OR REPLACE FUNCTION cs_find_referrer_type(v_host IN VARCHAR,
        v_domain IN VARCHAR, v_url IN VARCHAR) RETURN VARCHAR IS BEGIN';
    FOR referrer_key IN referrer_keys LOOP
        func_cmd := func_cmd ||
            ' IF v_' || referrer_key.kind
            || ' LIKE ' || quote_literal(referrer_key.key_string)
            || ' THEN RETURN ' || referrer_key.referrer_type
            || ' END IF;';
    END LOOP;
    func_cmd := func_cmd || ' RETURN NULL; END;';
    EXECUTE IMMEDIATE func_cmd;
END;
/
show errors;
```

Here is how this function would end up in PostgreSQL:

```sql
CREATE OR REPLACE FUNCTION cs_update_referrer_type_proc() RETURNS void AS $func$
DECLARE
    referrer_key RECORD; -- declare a generic record to be used in a FOR
    func_body text;
    func_cmd text;
BEGIN
    func_body := 'BEGIN';
    -- Notice how we scan through the results of a query in a FOR loop
    -- using the FOR <record> construct.
    FOR referrer_key IN SELECT * FROM cs_referrer_keys ORDER BY try_order LOOP
        func_body := func_body ||
            ' IF v_' || referrer_key.kind
            || ' LIKE ' || quote_literal(referrer_key.key_string)
```
Chapter 38. PL/pgSQL - SQL Procedural Language

|| ' THEN RETURN ' || quote_literal(referrer_key.referrer_type) || '; END IF;' ;
END LOOP;

func_body := func_body || ' RETURN NULL; END;' ;

func_cmd :=
'CREATE OR REPLACE FUNCTION cs_find_referrer_type(v_host varchar,
 v_domain varchar,
 v_url varchar)
 RETURNS varchar AS ' || quote_literal(func_body) || ' LANGUAGE plpgsql;' ;

EXECUTE func_cmd;

END;

$func$ LANGUAGE plpgsql;

Notice how the body of the function is built separately and passed through quote_literal to double any quote marks in it. This technique is needed because we cannot safely use dollar quoting for defining the new function: we do not know for sure what strings will be interpolated from the referrer_key.key_string field. (We are assuming here that referrer_key.kind can be trusted to always be host, domain, or url, but referrer_key.key_string might be anything, in particular it might contain dollar signs.) This function is actually an improvement on the Oracle original, because it will not generate broken code when referrer_key.key_string or referrer_key.referrer_type contain quote marks.

Example 38-7 shows how to port a function with OUT parameters and string manipulation. PostgreSQL does not have a built-in instr function, but you can create one using a combination of other functions. In Section 38.12.3 there is a PL/pgSQL implementation of instr that you can use to make your porting easier.

Example 38-7. Porting a Procedure With String Manipulation and OUT Parameters from PL/SQL to PL/pgSQL

The following Oracle PL/SQL procedure is used to parse a URL and return several elements (host, path, and query).

This is the Oracle version:

CREATE OR REPLACE PROCEDURE cs_parse_url(
 v_url IN VARCHAR,
 v_host OUT VARCHAR, -- This will be passed back
 v_path OUT VARCHAR, -- This one too
 v_query OUT VARCHAR) -- And this one
IS
 a_pos1 INTEGER;
 a_pos2 INTEGER;
BEGIN
 v_host := NULL;
 v_path := NULL;
 v_query := NULL;
 a_pos1 := instr(v_url, '//');

 IF a_pos1 = 0 THEN
 RETURN;

 Example 38-7 shows how to port a function with OUT parameters and string manipulation. PostgreSQL does not have a built-in instr function, but you can create one using a combination of other functions. In Section 38.12.3 there is a PL/pgSQL implementation of instr that you can use to make your porting easier.

 Example 38-7. Porting a Procedure With String Manipulation and OUT Parameters from PL/SQL to PL/pgSQL

 The following Oracle PL/SQL procedure is used to parse a URL and return several elements (host, path, and query).

 This is the Oracle version:

 CREATE OR REPLACE PROCEDURE cs_parse_url(
   v_url IN VARCHAR,
   v_host OUT VARCHAR, -- This will be passed back
   v_path OUT VARCHAR, -- This one too
   v_query OUT VARCHAR) -- And this one
   IS
     a_pos1 INTEGER;
     a_pos2 INTEGER;
   BEGIN
     v_host := NULL;
     v_path := NULL;
     v_query := NULL;
     a_pos1 := instr(v_url, '//');

     IF a_pos1 = 0 THEN
       RETURN;

     func_body := func_body || ' RETURN NULL; END;' ;

     func_cmd :=
       'CREATE OR REPLACE FUNCTION cs_find_referrer_type(v_host varchar,
         v_domain varchar,
         v_url varchar)
         RETURNS varchar AS ' || quote_literal(func_body) || ' LANGUAGE plpgsql;' ;

     EXECUTE func_cmd;

     END;

     END;

     $func$ LANGUAGE plpgsql;

 Notice how the body of the function is built separately and passed through quote_literal to double any quote marks in it. This technique is needed because we cannot safely use dollar quoting for defining the new function: we do not know for sure what strings will be interpolated from the referrer_key.key_string field. (We are assuming here that referrer_key.kind can be trusted to always be host, domain, or url, but referrer_key.key_string might be anything, in particular it might contain dollar signs.) This function is actually an improvement on the Oracle original, because it will not generate broken code when referrer_key.key_string or referrer_key.referrer_type contain quote marks.

 Example 38-7 shows how to port a function with OUT parameters and string manipulation. PostgreSQL does not have a built-in instr function, but you can create one using a combination of other functions. In Section 38.12.3 there is a PL/pgSQL implementation of instr that you can use to make your porting easier.
Chapter 38. PL/pgSQL - SQL Procedural Language

END IF;

END;

Here is a possible translation into PL/pgSQL:

CREATE OR REPLACE FUNCTION cs_parse_url(
    v_url IN VARCHAR,
    v_host OUT VARCHAR, -- This will be passed back
    v_path OUT VARCHAR, -- This one too
    v_query OUT VARCHAR) -- And this one
AS $$
DECLARE
    a_pos1 INTEGER;
    a_pos2 INTEGER;
BEGIN
    v_host := NULL;
    v_path := NULL;
    v_query := NULL;
    a_pos1 := instr(v_url, '//');

    IF a_pos1 = 0 THEN
        RETURN;
    END IF;

    a_pos2 := instr(v_url, '/', a_pos1 + 2);
    IF a_pos2 = 0 THEN
        v_host := substr(v_url, a_pos1 + 2);
        v_path := '/';
        RETURN;
    END IF;

    v_host := substr(v_url, a_pos1 + 2, a_pos2 - a_pos1 - 2);
    a_pos1 := instr(v_url, '?', a_pos2 + 1);

    IF a_pos1 = 0 THEN
        v_path := substr(v_url, a_pos2);
        RETURN;
    END IF;

    v_path := substr(v_url, a_pos2, a_pos1 - a_pos2);
    v_query := substr(v_url, a_pos1 + 1);
END;
/

show errors;
Chapter 38. PL/pgSQL - SQL Procedural Language

This function could be used like this:

```sql
SELECT * FROM cs_parse_url('http://foobar.com/query.cgi?baz');
```

Example 38-8 shows how to port a procedure that uses numerous features that are specific to Oracle.

**Example 38-8. Porting a Procedure from PL/SQL to PL/pgSQL**

The Oracle version:

```sql
CREATE OR REPLACE PROCEDURE cs_create_job(v_job_id IN INTEGER) IS
  a_running_job_count INTEGER;
  PRAGMA AUTONOMOUS_TRANSACTION;
BEGIN
  LOCK TABLE cs_jobs IN EXCLUSIVE MODE;

  SELECT count(*) INTO a_running_job_count FROM cs_jobs WHERE end_stamp IS NULL;

  IF a_running_job_count > 0 THEN
    COMMIT; -- free lock
    RAISE_APPLICATION_ERROR(-20000, 'Unable to create a new job: a job is currently running.');</n
  END IF;

  DELETE FROM cs_active_job;
  INSERT INTO cs_active_job(job_id) VALUES (v_job_id);

  BEGIN
    INSERT INTO cs_jobs (job_id, start_stamp) VALUES (v_job_id, sysdate);
  EXCEPTION
    WHEN dup_val_on_index THEN NULL; -- don’t worry if it already exists
  END;
  COMMIT;
END;
/
```

Procedures like this can easily be converted into PostgreSQL functions returning `void`. This procedure in particular is interesting because it can teach us some things:

1. There is no `PRAGMA` statement in PostgreSQL.
2. If you do a `LOCK TABLE` in PL/pgSQL, the lock will not be released until the calling transaction is finished.
3. You cannot issue `COMMIT` in a PL/pgSQL function. The function is running within some outer transaction and so `COMMIT` would imply terminating the function’s execution. However, in this particular case it is not necessary anyway, because the lock obtained by the `LOCK TABLE` will be released when we raise an error.

This is how we could port this procedure to PL/pgSQL:

```sql
CREATE OR REPLACE FUNCTION cs_create_job(v_job_id integer) RETURNS void AS $$
DECLARE
  a_running_job_count integer;
BEGIN
  LOCK TABLE cs_jobs IN EXCLUSIVE MODE;

  SELECT count(*) INTO a_running_job_count FROM cs_jobs WHERE end_stamp IS NULL;

  IF a_running_job_count > 0 THEN
    COMMIT; -- free lock
    RAISE_APPLICATION_ERROR(-20000, 'Unable to create a new job: a job is currently running.');</n
  END IF;

  DELETE FROM cs_active_job;
  INSERT INTO cs_active_job(job_id) VALUES (v_job_id);

  BEGIN
    INSERT INTO cs_jobs (job_id, start_stamp) VALUES (v_job_id, sysdate);
  EXCEPTION
    WHEN dup_val_on_index THEN NULL; -- don’t worry if it already exists
  END;
  COMMIT;
END;
$$;
```

767
BEGIN
  LOCK TABLE cs_jobs IN EXCLUSIVE MODE;

  SELECT count(*) INTO a_running_job_count FROM cs_jobs WHERE end_stamp IS NULL;

  IF a_running_job_count > 0 THEN
    RAISE EXCEPTION 'Unable to create a new job: a job is currently running';  
  END IF;

  DELETE FROM cs_active_job;
  INSERT INTO cs_active_job(job_id) VALUES (v_job_id);

  BEGIN
    INSERT INTO cs_jobs (job_id, start_stamp) VALUES (v_job_id, now());
  EXCEPTION
    WHEN unique_violation THEN
      -- don't worry if it already exists
  END;
END;
$$ LANGUAGE plpgsql;

1. The syntax of RAISE is considerably different from Oracle’s similar statement.
2. The exception names supported by PL/pgSQL are different from Oracle’s. The set of built-in exception names is much larger (see Appendix A). There is not currently a way to declare user-defined exception names.

The main functional difference between this procedure and the Oracle equivalent is that the exclusive lock on the cs_jobs table will be held until the calling transaction completes. Also, if the caller later aborts (for example due to an error), the effects of this procedure will be rolled back.

38.12.2. Other Things to Watch For

This section explains a few other things to watch for when porting Oracle PL/SQL functions to PostgreSQL.

38.12.2.1. Implicit Rollback after Exceptions

In PL/pgSQL, when an exception is caught by an EXCEPTION clause, all database changes since the block’s BEGIN are automatically rolled back. That is, the behavior is equivalent to what you’d get in Oracle with:

BEGIN
  SAVEPOINT s1;
  ... code here ...
EXCEPTION
  WHEN ... THEN
    ROLLBACK TO s1;
    ... code here ...
  WHEN ... THEN
    ROLLBACK TO s1;
    ... code here ...
END;
If you are translating an Oracle procedure that uses `SAVEPOINT` and `ROLLBACK TO` in this style, your task is easy: just omit the `SAVEPOINT` and `ROLLBACK TO`. If you have a procedure that uses `SAVEPOINT` and `ROLLBACK TO` in a different way then some actual thought will be required.

### 38.12.2.2. EXECUTE

The PL/pgSQL version of `EXECUTE` works similarly to the PL/SQL version, but you have to remember to use `quote_literal` and `quote_ident` as described in Section 38.5.4. Constructs of the type `EXECUTE ‘SELECT * FROM $1’;` will not work reliably unless you use these functions.

### 38.12.2.3. Optimizing PL/pgSQL Functions

PostgreSQL gives you two function creation modifiers to optimize execution: “volatility” (whether the function always returns the same result when given the same arguments) and “strictness” (whether the function returns null if any argument is null). Consult the `CREATE FUNCTION` reference page for details.

When making use of these optimization attributes, your `CREATE FUNCTION` statement might look something like this:

```sql
CREATE FUNCTION foo(...) RETURNS integer AS $$
  ...
$$ LANGUAGE plpgsql STRICT IMMUTABLE;
```

### 38.12.3. Appendix

This section contains the code for a set of Oracle-compatible `instr` functions that you can use to simplify your porting efforts.

```sql
-- instr functions that mimic Oracle’s counterpart
-- Syntax: instr(string1, string2, [n], [m]) where [] denotes optional parameters.
-- Searches string1 beginning at the nth character for the mth occurrence
-- of string2. If n is negative, search backwards. If m is not passed,
-- assume 1 (search starts at first character).

CREATE FUNCTION instr(varchar, varchar) RETURNS integer AS $$
  DECLARE
    pos integer;
  BEGIN
    pos := instr($1, $2, 1);
    RETURN pos;
  END;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;

CREATE FUNCTION instr(string varchar, string_to_search varchar, beg_index integer)
  RETURNS integer AS $$
```

769
DECLARE
pos integer NOT NULL DEFAULT 0;
temp_str varchar;
beg integer;
length integer;
ss_length integer;
BEGIN
IF beg_index > 0 THEN
    temp_str := substring(string FROM beg_index);
    pos := position(string_to_search IN temp_str);
    IF pos = 0 THEN
        RETURN 0;
    ELSE
        RETURN pos + beg_index - 1;
    END IF;
ELSE
    ss_length := char_length(string_to_search);
    length := char_length(string);
    beg := length + beg_index - ss_length + 2;
    WHILE beg > 0 LOOP
        temp_str := substring(string FROM beg FOR ss_length);
        pos := position(string_to_search IN temp_str);
        IF pos > 0 THEN
            RETURN beg;
        END IF;
        beg := beg - 1;
    END LOOP;
    RETURN 0;
END IF;
END;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;

CREATE FUNCTION instr(string varchar, string_to_search varchar,
beg_index integer, occur_index integer)
RETURNS integer AS $$
DECLARE
pos integer NOT NULL DEFAULT 0;
occur_number integer NOT NULL DEFAULT 0;
temp_str varchar;
beg integer;
i integer;
length integer;
ss_length integer;
BEGIN
    IF beg_index > 0 THEN
        beg := beg_index;
        temp_str := substring(string FROM beg_index);
        FOR i IN 1..occur_index LOOP
            pos := position(string_to_search IN temp_str);
        END LOOP;
    END IF;
END;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;
Chapter 38. PL/pgSQL - SQL Procedural Language

```
IF i = 1 THEN
    beg := beg + pos - 1;
ELSE
    beg := beg + pos;
END IF;

temp_str := substring(string FROM beg + 1);
END LOOP;

IF pos = 0 THEN
    RETURN 0;
ELSE
    RETURN beg;
END IF;
ELSE
    ss_length := char_length(string_to_search);
    length := char_length(string);
    beg := length + beg_index - ss_length + 2;

    WHILE beg > 0 LOOP
        temp_str := substring(string FROM beg FOR ss_length);
        pos := position(string_to_search IN temp_str);

        IF pos > 0 THEN
            occur_number := occur_number + 1;

            IF occur_number = occur_index THEN
                RETURN beg;
            END IF;
        END IF;
        beg := beg - 1;
    END LOOP;

    RETURN 0;
END IF;
END;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;
```
Chapter 39. PL/Tcl - Tcl Procedural Language

PL/Tcl is a loadable procedural language for the PostgreSQL database system that enables the Tcl language\(^1\) to be used to write functions and trigger procedures.

39.1. Overview

PL/Tcl offers most of the capabilities a function writer has in the C language, with a few restrictions, and with the addition of the powerful string processing libraries that are available for Tcl.

One compelling good restriction is that everything is executed from within the safety of the context of a Tcl interpreter. In addition to the limited command set of safe Tcl, only a few commands are available to access the database via SPI and to raise messages via `elog()`. PL/Tcl provides no way to access internals of the database server or to gain OS-level access under the permissions of the PostgreSQL server process, as a C function can do. Thus, unprivileged database users can be trusted to use this language; it does not give them unlimited authority.

The other notable implementation restriction is that Tcl functions cannot be used to create input/output functions for new data types.

Sometimes it is desirable to write Tcl functions that are not restricted to safe Tcl. For example, one might want a Tcl function that sends email. To handle these cases, there is a variant of PL/Tcl called PL/TclU (for untrusted Tcl). This is the exact same language except that a full Tcl interpreter is used. If PL/TclU is used, it must be installed as an untrusted procedural language so that only database superusers can create functions in it. The writer of a PL/TclU function must take care that the function cannot be used to do anything unwanted, since it will be able to do anything that could be done by a user logged in as the database administrator.

The shared object code for the PL/Tcl and PL/TclU call handlers is automatically built and installed in the PostgreSQL library directory if Tcl support is specified in the configuration step of the installation procedure. To install PL/Tcl and/or PL/TclU in a particular database, use the `createlang` program, for example `createlang pltcl dbname` or `createlang pltclu dbname`.

39.2. PL/Tcl Functions and Arguments

To create a function in the PL/Tcl language, use the standard `CREATE FUNCTION` syntax:

```
CREATE FUNCTION funcname (argument-types) RETURNS return-type AS $$
# PL/Tcl function body
$$ LANGUAGE pltcl;
```

PL/TclU is the same, except that the language has to be specified as `pltclu`.

The body of the function is simply a piece of Tcl script. When the function is called, the argument values are passed as variables `$1` ... `$n` to the Tcl script. The result is returned from the Tcl code in the usual way, with a `return` statement.

For example, a function returning the greater of two integer values could be defined as:

```
CREATE FUNCTION tcl_max(integer, integer) RETURNS integer AS $$
if ($1 > $2) {return $1}
return $2
$$
```

---

1. http://www.tcl.tk/
Note the clause **STRICT**, which saves us from having to think about null input values: if a null value is passed, the function will not be called at all, but will just return a null result automatically.

In a nonstrict function, if the actual value of an argument is null, the corresponding $n variable will be set to an empty string. To detect whether a particular argument is null, use the function `argisnull`. For example, suppose that we wanted `tcl_max` with one null and one nonnull argument to return the nonnull argument, rather than null:

```tcl
CREATE FUNCTION tcl_max(integer, integer) RETURNS integer AS $$
    if {[argisnull 1]} {
        if {[argisnull 2]} { return_null }
        return $2
    }
    if {[argisnull 2]} { return $1 }
    if {$1 > $2} {return $1}
    return $2
$$ LANGUAGE pltcl;
```

As shown above, to return a null value from a PL/Tcl function, execute `return_null`. This can be done whether the function is strict or not.

Composite-type arguments are passed to the function as Tcl arrays. The element names of the array are the attribute names of the composite type. If an attribute in the passed row has the null value, it will not appear in the array. Here is an example:

```tcl
CREATE TABLE employee {
    name text,
    salary integer,
    age integer
};

CREATE FUNCTION overpaid(employee) RETURNS boolean AS $$
    if {200000.0 < $1(salary)} {
        return "t"
    }
    if {$1(age) < 30 && 100000.0 < $1(salary)} {
        return "t"
    }
    return "f"
$$ LANGUAGE pltcl;
```

There is currently no support for returning a composite-type result value, nor for returning sets.

PL/Tcl does not currently have full support for domain types: it treats a domain the same as the underlying scalar type. This means that constraints associated with the domain will not be enforced. This is not an issue for function arguments, but it is a hazard if you declare a PL/Tcl function as returning a domain type.
39.3. Data Values in PL/Tcl

The argument values supplied to a PL/Tcl function’s code are simply the input arguments converted to text form (just as if they had been displayed by a SELECT statement). Conversely, the return command will accept any string that is acceptable input format for the function’s declared return type. So, within the PL/Tcl function, all values are just text strings.

39.4. Global Data in PL/Tcl

Sometimes it is useful to have some global data that is held between two calls to a function or is shared between different functions. This is easily done in PL/Tcl, but there are some restrictions that must be understood.

For security reasons, PL/Tcl executes functions called by any one SQL role in a separate Tcl interpreter for that role. This prevents accidental or malicious interference by one user with the behavior of another user’s PL/Tcl functions. Each such interpreter will have its own values for any “global” Tcl variables. Thus, two PL/Tcl functions will share the same global variables if and only if they are executed by the same SQL role. In an application wherein a single session executes code under multiple SQL roles (via SECURITY DEFINER functions, use of SET ROLE, etc) you may need to take explicit steps to ensure that PL/Tcl functions can share data. To do that, make sure that functions that should communicate are owned by the same user, and mark them SECURITY DEFINER. You must of course take care that such functions can’t be used to do anything unintended.

All PL/Tcl functions used in a session execute in the same Tcl interpreter, which of course is distinct from the interpreter(s) used for PL/Tcl functions. So global data is automatically shared between PL/Tcl functions. This is not considered a security risk because all PL/Tcl functions execute at the same trust level, namely that of a database superuser.

To help protect PL/Tcl functions from unintentionally interfering with each other, a global array is made available to each function via the upvar command. The global name of this variable is the function’s internal name, and the local name is GD. It is recommended that GD be used for persistent private data of a function. Use regular Tcl global variables only for values that you specifically intend to be shared among multiple functions. (Note that the GD arrays are only global within a particular interpreter, so they do not bypass the security restrictions mentioned above.)

An example of using GD appears in the spi_execp example below.

39.5. Database Access from PL/Tcl

The following commands are available to access the database from the body of a PL/Tcl function:

```
spi_exec ?-count n? ?-array name? command ?-loop-body?
```

Executes an SQL command given as a string. An error in the command causes an error to be raised. Otherwise, the return value of spi_exec is the number of rows processed (selected, inserted, updated, or deleted) by the command, or zero if the command is a utility statement. In addition, if the command is a SELECT statement, the values of the selected columns are placed in Tcl variables as described below.

The optional -count value tells spi_exec the maximum number of rows to process in the command. The effect of this is comparable to setting up a query as a cursor and then saying FETCH n.
If the command is a `SELECT` statement, the values of the result columns are placed into Tcl variables named after the columns. If the `-array` option is given, the column values are instead stored into the named associative array, with the column names used as array indexes.

If the command is a `SELECT` statement and no `loop-body` script is given, then only the first row of results are stored into Tcl variables; remaining rows, if any, are ignored. No storing occurs if the query returns no rows. (This case can be detected by checking the result of `spi_exec`.) For example:

```tcl
spi_exec "SELECT count(*) AS cnt FROM pg_proc"
```

will set the Tcl variable `$cnt` to the number of rows in the `pgProc` system catalog.

If the optional `loop-body` argument is given, it is a piece of Tcl script that is executed once for each row in the query result. (`loop-body` is ignored if the given command is not a `SELECT`.) The values of the current row’s columns are stored into Tcl variables before each iteration. For example:

```tcl
spi_exec -array C "SELECT * FROM pg_class" {
  elog DEBUG "have table $C(relname)"
}
```

will print a log message for every row of `pg_class`. This feature works similarly to other Tcl looping constructs; in particular `continue` and `break` work in the usual way inside the loop body.

If a column of a query result is null, the target variable for it is “unset” rather than being set.

```tcl
spi_prepare query typelist
```

Prepares and saves a query plan for later execution. The saved plan will be retained for the life of the current session.

The query can use parameters, that is, placeholders for values to be supplied whenever the plan is actually executed. In the query string, refer to parameters by the symbols `$1` ... `$n`. If the query uses parameters, the names of the parameter types must be given as a Tcl list. (Write an empty list for `typelist` if no parameters are used.)

The return value from `spi_prepare` is a query ID to be used in subsequent calls to `spi_execp`. See `spi_execp` for an example.

```tcl
```

Executes a query previously prepared with `spi_prepare`. `queryid` is the ID returned by `spi_prepare`. If the query references parameters, a `value-list` must be supplied. This is a Tcl list of actual values for the parameters. The list must be the same length as the parameter type list previously given to `spi_prepare`. `Omit value-list` if the query has no parameters.

The optional value for `-nulls` is a string of spaces and `'n'` characters telling `spi_execp` which of the parameters are null values. If given, it must have exactly the same length as the `value-list`. If it is not given, all the parameter values are nonnull.

Except for the way in which the query and its parameters are specified, `spi_execp` works just like `spi_exec`. The `-count`, `-array`, and `loop-body` options are the same, and so is the result value.

Here’s an example of a PL/Tcl function using a prepared plan:

```tcl
CREATE FUNCTION t1_count(integer, integer) RETURNS integer AS $$
  if {! [info exists GD(plan) ]} {
    # prepare the saved plan on the first call
    set GD(plan) [ spi_prepare "SELECT count(*) AS cnt FROM t1 WHERE num >= \$1 AND num <= \$2" \
```
spi_execp

```
spi_execp -count 1 $GD(plan) [ list $1 $2 ]
return $cnt
```

```$ LANGUAGE pltcl;
We need backslashes inside the query string given to spi_prepare to ensure that the $n markers will be passed through to spi_prepare as-is, and not replaced by Tcl variable substitution.
```

spi_lastoid

Returns the OID of the row inserted by the last spi_exec or spi_execp, if the command was a single-row INSERT and the modified table contained OIDs. (If not, you get zero.)

```
quote string

Doubles all occurrences of single quote and backslash characters in the given string. This can be used to safely quote strings that are to be inserted into SQL commands given to spi_exec or spi_prepare. For example, think about an SQL command string like:

"SELECT '$val' AS ret"

where the Tcl variable val actually contains doesn’t. This would result in the final command string:

SELECT 'doesn’t' AS ret

which would cause a parse error during spi_exec or spi_prepare. To work properly, the submitted command should contain:

SELECT 'doesn”t' AS ret

which can be formed in PL/Tcl using:

"SELECT [ quote $val ]' AS ret"

One advantage of spi_execp is that you don’t have to quote parameter values like this, since the parameters are never parsed as part of an SQL command string.

elog level msg

Emits a log or error message. Possible levels are DEBUG, LOG, INFO, NOTICE, WARNING, ERROR, and FATAL. ERROR raises an error condition; if this is not trapped by the surrounding Tcl code, the error propagates out to the calling query, causing the current transaction or subtransaction to be aborted. This is effectively the same as the Tcl error command. FATAL aborts the transaction and causes the current session to shut down. (There is probably no good reason to use this error level in PL/Tcl functions, but it’s provided for completeness.) The other levels only generate messages of different priority levels. Whether messages of a particular priority are reported to the client, written to the server log, or both is controlled by the log_min_messages and client_min_messages configuration variables. See Chapter 18 for more information.

39.6. Trigger Procedures in PL/Tcl

Trigger procedures can be written in PL/Tcl. PostgreSQL requires that a procedure that is to be called as a trigger must be declared as a function with no arguments and a return type of trigger.

The information from the trigger manager is passed to the procedure body in the following variables:

```
$TG_name
```

The name of the trigger from the CREATE TRIGGER statement.
$TG_relid
The object ID of the table that caused the trigger procedure to be invoked.

$TG_table_name
The name of the table that caused the trigger procedure to be invoked.

$TG_table_schema
The schema of the table that caused the trigger procedure to be invoked.

$TG_relatts
A Tcl list of the table column names, prefixed with an empty list element. So looking up a column name in the list with Tcl’s lsearch command returns the element’s number starting with 1 for the first column, the same way the columns are customarily numbered in PostgreSQL. (Empty list elements also appear in the positions of columns that have been dropped, so that the attribute numbering is correct for columns to their right.)

$TG_when
The string \texttt{BEFORE} or \texttt{AFTER} depending on the type of trigger call.

$TG_level
The string \texttt{ROW} or \texttt{STATEMENT} depending on the type of trigger call.

$TG_op
The string \texttt{INSERT}, \texttt{UPDATE}, or \texttt{DELETE} depending on the type of trigger call.

$NEW
An associative array containing the values of the new table row for \texttt{INSERT} or \texttt{UPDATE} actions, or empty for \texttt{DELETE}. The array is indexed by column name. Columns that are null will not appear in the array.

$OLD
An associative array containing the values of the old table row for \texttt{UPDATE} or \texttt{DELETE} actions, or empty for \texttt{INSERT}. The array is indexed by column name. Columns that are null will not appear in the array.

$args
A Tcl list of the arguments to the procedure as given in the \texttt{CREATE TRIGGER} statement. These arguments are also accessible as \$1 ... \$n in the procedure body.

The return value from a trigger procedure can be one of the strings \texttt{OK} or \texttt{SKIP}, or a list as returned by the array get Tcl command. If the return value is \texttt{OK}, the operation (\texttt{INSERT/UPDATE/DELETE}) that fired the trigger will proceed normally. \texttt{SKIP} tells the trigger manager to silently suppress the operation for this row. If a list is returned, it tells PL/Tcl to return a modified row to the trigger manager that will be inserted instead of the one given in $NEW. (This works for \texttt{INSERT} and \texttt{UPDATE} only.) Needless to say that all this is only meaningful when the trigger is \texttt{BEFORE} and \texttt{FOR EACH ROW}; otherwise the return value is ignored.

Here’s a little example trigger procedure that forces an integer value in a table to keep track of the number of updates that are performed on the row. For new rows inserted, the value is initialized to 0 and then incremented on every update operation.

\begin{verbatim}
CREATE FUNCTION trigfunc_modcount() RETURNS trigger AS $$
switch $TG_op {
   INSERT {
      $NEW[modcount] = 0;
      $NEW[modcount] = $NEW[modcount] + 1;
   };
   UPDATE {
      $NEW[modcount] = 0;
      $NEW[modcount] = $NEW[modcount] + 1;
   };
   DELETE {
      $OLD[modcount] = 0;
      $OLD[modcount] = $OLD[modcount] - 1;
   };
}$$;
\end{verbatim}
Chapter 39. PL/Tcl - Tcl Procedural Language

```
set NEW($1) 0
}
UPDATE {
    set NEW($1) $OLD($1)
    incr NEW($1)
}
default {
    return OK
}
return [array get NEW]
```

```bash
$$ LANGUAGE pltcl;

CREATE TABLE mytab (num integer, description text, modcnt integer);
CREATE TRIGGER trig_mytab_modcount BEFORE INSERT OR UPDATE ON mytab
    FOR EACH ROW EXECUTE PROCEDURE trigfunc_modcount('modcnt');
```

Notice that the trigger procedure itself does not know the column name; that’s supplied from the trigger arguments. This lets the trigger procedure be reused with different tables.

### 39.7. Modules and the `unknown` command

PL/Tcl has support for autoloading Tcl code when used. It recognizes a special table, `pltcl_modules`, which is presumed to contain modules of Tcl code. If this table exists, the module `unknown` is fetched from the table and loaded into the Tcl interpreter immediately before the first execution of a PL/Tcl function in a database session. (This happens separately for each Tcl interpreter, if more than one is used in a session; see Section 39.4.)

While the `unknown` module could actually contain any initialization script you need, it normally defines a Tcl `unknown` procedure that is invoked whenever Tcl does not recognize an invoked procedure name. PL/Tcl’s standard version of this procedure tries to find a module in `pltcl_modules` that will define the required procedure. If one is found, it is loaded into the interpreter, and then execution is allowed to proceed with the originally attempted procedure call. A secondary table `pltcl_modfuncs` provides an index of which functions are defined by which modules, so that the lookup is reasonably quick.

The PostgreSQL distribution includes support scripts to maintain these tables: `pltcl_loadmod`, `pltcl_listmod`, `pltcl_delmod`, as well as source for the standard `unknown` module in `share/unknown.pltcl`. This module must be loaded into each database initially to support the autoloading mechanism.

The tables `pltcl_modules` and `pltcl_modfuncs` must be readable by all, but it is wise to make them owned and writable only by the database administrator. As a security precaution, PL/Tcl will ignore `pltcl_modules` (and thus, not attempt to load the `unknown` module) unless it is owned by a superuser. But update privileges on this table can be granted to other users, if you trust them sufficiently.

### 39.8. Tcl Procedure Names

In PostgreSQL, the same function name can be used for different function definitions as long as the number of arguments or their types differ. Tcl, however, requires all procedure names to be distinct.
PL/Tcl deals with this by making the internal Tcl procedure names contain the object ID of the function from the system table `pg_proc` as part of their name. Thus, PostgreSQL functions with the same name and different argument types will be different Tcl procedures, too. This is not normally a concern for a PL/Tcl programmer, but it might be visible when debugging.
Chapter 40. PL/Perl - Perl Procedural Language

PL/Perl is a loadable procedural language that enables you to write PostgreSQL functions in the Perl programming language\(^1\).

The usual advantage to using PL/Perl is that this allows use, within stored functions, of the manyfold “string munging” operators and functions available for Perl. Parsing complex strings might be easier using Perl than it is with the string functions and control structures provided in PL/pgSQL.

To install PL/Perl in a particular database, use `createlang plperl dbname`.

**Tip:** If a language is installed into `template1`, all subsequently created databases will have the language installed automatically.

**Note:** Users of source packages must specially enable the build of PL/Perl during the installation process. (Refer to Chapter 15 for more information.) Users of binary packages might find PL/Perl in a separate subpackage.

### 40.1. PL/Perl Functions and Arguments

To create a function in the PL/Perl language, use the standard `CREATE FUNCTION` syntax:

```sql
CREATE FUNCTION funcname (argument-types) RETURNS return-type AS $$
    # PL/Perl function body
$$ LANGUAGE plperl;
```

The body of the function is ordinary Perl code. In fact, the PL/Perl glue code wraps it inside a Perl subroutine. A PL/Perl function must always return a scalar value. You can return more complex structures (arrays, records, and sets) by returning a reference, as discussed below. Never return a list.

**Note:** The use of named nested subroutines is dangerous in Perl, especially if they refer to lexical variables in the enclosing scope. Because a PL/Perl function is wrapped in a subroutine, any named subroutine you create will be nested. In general, it is far safer to create anonymous subroutines which you call via a coderef. See the `perldiag` man page for more details.

The syntax of the `CREATE FUNCTION` command requires the function body to be written as a string constant. It is usually most convenient to use dollar quoting (see Section 4.1.2.2) for the string constant. If you choose to use escape string syntax `E"`, you must double any single quote marks (`'`) and backslashes (`\`) used in the body of the function (see Section 4.1.2.1).

Arguments and results are handled as in any other Perl subroutine: arguments are passed in `@_`, and a result value is returned with `return` or as the last expression evaluated in the function.

For example, a function returning the greater of two integer values could be defined as:

```sql
CREATE FUNCTION perl_max (integer, integer) RETURNS integer AS $$
    # PL/Perl function body
$$ LANGUAGE plperl;
```

---

1. [http://www.perl.com](http://www.perl.com)

780
Chapter 40. PL/Perl - Perl Procedural Language

if ($_[0] > $_[1]) { return $_[0]; }
return $_[1];

```plperl
my ($x,$y) = @_; if (! defined $x) { if (! defined $y) { return undef; } return $y; }
if (! defined $y) { return $x; }
if ($x > $y) { return $x; }
return $y;
```

As shown above, to return an SQL null value from a PL/Perl function, return an undefined value. This can be done whether the function is strict or not.

Anything in a function argument that is not a reference is a string, which is in the standard PostgreSQL external text representation for the relevant data type. In the case of ordinary numeric or text types, Perl will just do the right thing and the programmer will normally not have to worry about it. However, in other cases the argument will need to be converted into a form that is more usable in Perl. For example, here is how to convert an argument of type `bytea` into unescaped binary data:

```perl
my $arg = shift;
$arg =~ s!(\|[^ -~])!chr(oct($1))!ge;
```

Similarly, values passed back to PostgreSQL must be in the external text representation format. For example, here is how to escape binary data for a return value of type `bytea`:

```perl
$retval =~ s!(\|[^ -~])!sprintf("\%03o",ord($1))!ge;
return $retval;
```

Perl can return PostgreSQL arrays as references to Perl arrays. Here is an example:

```plperl
CREATE OR REPLACE function returns_array()
RETURNS text[][] AS $$
  return [ ['a''b','c,d'], ['e\f','g'] ];
$$ LANGUAGE plperl;

select returns_array();
```
Composite-type arguments are passed to the function as references to hashes. The keys of the hash are the attribute names of the composite type. Here is an example:

```sql
CREATE TABLE employee {
    name text,
    basesalary integer,
    bonus integer
};

CREATE FUNCTION empcomp(employee) RETURNS integer AS $$
my ($emp) = @_; 
return $emp->{basesalary} + $emp->{bonus};$$ LANGUAGE plperl;

SELECT name, empcomp(employee.*) FROM employee;
```

A PL/Perl function can return a composite-type result using the same approach: return a reference to a hash that has the required attributes. For example:

```sql
CREATE TYPE testrowperl AS (f1 integer, f2 text, f3 text);

CREATE OR REPLACE FUNCTION perl_row() RETURNS testrowperl AS $$
return {f2 = 'hello', f1 = 1, f3 = 'world'};
$$ LANGUAGE plperl;

SELECT * FROM perl_row();
```

Any columns in the declared result data type that are not present in the hash will be returned as null values.

PL/Perl functions can also return sets of either scalar or composite types. Usually you’ll want to return rows one at a time, both to speed up startup time and to keep from queueing up the entire result set in memory. You can do this with `return_next` as illustrated below. Note that after the last `return_next`, you must put either `return` or (better) `return undef`.

```sql
CREATE OR REPLACE FUNCTION perl_set_int(int)
RETURNS SETOF INTEGER AS $$
foreach (0..$_[0]) {
    return_next($_);
} 
return undef;
$$ LANGUAGE plperl;

SELECT * FROM perl_set_int(5);
```

For small result sets, you can return a reference to an array that contains either scalars, references to arrays, or references to hashes for simple types, array types, and composite types, respectively. Here are some simple examples of returning the entire result set as an array reference:

```sql
CREATE OR REPLACE FUNCTION perl_set() 
RETURNS SETOF testrowperl AS $$
return_next({ f1 => 1, f2 => 'Hello', f3 => 'World' });
return_next({ f1 => 2, f2 => 'Hello', f3 => 'PostgreSQL' });
return_next({ f1 => 3, f2 => 'Hello', f3 => 'PL/Perl' });
return undef;
$$ LANGUAGE plperl;

SELECT * FROM perl_set();
```
CREATE OR REPLACE FUNCTION perl_set_int(int) RETURNS SETOF INTEGER AS $$
return [0..$_[0]]; $$ LANGUAGE plperl;

SELECT * FROM perl_set_int(5);

CREATE OR REPLACE FUNCTION perl_set() RETURNS SETOF testrowperl AS $$
return [
    { f1 => 1, f2 => 'Hello', f3 => 'World' },
    { f1 => 2, f2 => 'Hello', f3 => 'PostgreSQL' },
    { f1 => 3, f2 => 'Hello', f3 => 'PL/Perl' }
]; $$ LANGUAGE plperl;

SELECT * FROM perl_set();

If you wish to use the strict pragma with your code, the easiest way to do so is to SET plperl.use_strict to true. This parameter affects subsequent compilations of PL/Perl functions, but not functions already compiled in the current session. To set the parameter before PL/Perl has been loaded, it is necessary to have added “plperl” to the custom_variable_classes list in postgresql.conf.

Another way to use the strict pragma is to put:

use strict;

in the function body.

### 40.2. Database Access from PL/Perl

Access to the database itself from your Perl function can be done via the function `spi_exec_query` described below, or via an experimental module `DBD::PgSPI` (also available at CPAN mirror sites). This module makes available a DBI-compliant database-handle named `$pg_dbh` that can be used to perform queries with normal DBI syntax.

PL/Perl provides additional Perl commands:

```
spi_exec_query(query [, max-rows])
spi_query(command)
spi_fetchrow(cursor)
spi_prepare(command, argument types)
spi_exec_prepared(plan)
spi_query_prepared(plan [, attributes], arguments)
spi_cursor_close(cursor)
spi_freeplan(plan)
```
